

Negative Equity, Household Debt Overhang, and Labor Supply

BY ASAF BERNSTEIN*

I shed new light on the role house price declines play in labor markets by examining the effect of negative home equity on labor supply decisions utilizing a new U.S. household-level dataset from 2010-2014 and plausibly exogenous variation based on timing of home purchases. I find that negative equity causes a 2%-6% reduction in household labor supply, with larger 2nd income elasticities. These results are robust to the inclusion of time-varying national cohort fixed effects as well as using a life-event driven proxy for the timing of home purchase based on the date of college attendance. I then identify a new component of this effect, “household debt overhang”, wherein income-contingent mortgage renegotiations act like implicit taxes, resulting in labor supply disincentives. When comparing MSAs just across state borders, effects are concentrated in states with discontinuously higher mortgage modification rates, consistent with a significant role played by this channel. Taken together these results provide evidence that a fall in house prices can exacerbate employment declines and highlights the potential unintended consequences of mortgage assistance programs. *JEL Codes: D10, G21, E44, J22, L85, R20*

*University of Colorado at Boulder – Leeds School of Business; 995 Regent Drive Boulder, CO 80302; Email: (email: asaf.bernstein@colorado.edu). I am grateful to Antoinette Schoar, Jonathan Parker, Deborah Lucas, and Nittai Bergman for their feedback and guidance throughout this project. I would also like to thank Andrew Lo, Adrien Verdelhan, Xavier Giroud, Tony Cookson, Daan Struyven, Daniel Green, Stephen Murphy, Nils Wernerfelt, and seminar participants at MIT Sloan, Berkeley Haas School of Business, Carnegie Mellon Tepper School of Business, Columbia Business School, Copenhagen Business School, Cornell Bi-Annual Household Behavioral Finance Symposium, Harvard Business School, Kellogg School of Management, NYU Stern School of Business, UCLA Anderson School of Management, UNC Kenan-Flagler Business School, University of Colorado at Boulder - Leeds School of Business, USC Marshall School of Business, Utah Eccles School of Business, Wharton, WUSTL Olin Business School, Yale School of Management, 2016 Stanford Institute of Theoretical Economics, and 2016 Western Finance Association Annual Meetings for helpful comments. Special thanks to the institution that provided data for this project. I was an unpaid intern at the institution during the time of this research, but any conclusions or errors herein are mine and do not represent the views of the data provider or any employees of that firm.

Following the historic decline in house prices during the recent financial crisis more than 15 million U.S. mortgages, or approximately 1/3rd of mortgaged properties, had negative home equity¹. At the same time, labor markets experienced a severe and prolonged deterioration, with employment still below pre-recession levels for years after the crisis. A number of theoretical papers (Stein 1995, Mulligan 2008, 2009, and 2010, Herkenhoff and Ohanian 2011, Donaldson, Piacentino, and Thakor 2017) have argued that this may have been at least partially driven by a casual effect of negative home equity on household labor supply decisions coming via contractual frictions that occur when mortgage liabilities exceed the value of the underlying property. In this paper I provide the first casual empirical estimates of the effect of negative home equity on household labor supply and find that instrumented negative equity is associated with a 2.3%-6.3% reduction in household income. This reduction in labor supply appears to be driven by large changes in household labor decisions, such as reductions in employment, rather than effort supplied at existing jobs.

I then explore the mechanisms through which negative home equity alters labor supply decisions and find support for what I call the “household debt overhang” channel. As noted by Donaldson, Piacentino, and Thakor (2017), since households have limited liability, if housing collateral value falls below the outstanding mortgage balance, the recovery value for lenders in default can depend on the household’s income. Mulligan (2008, 2009, and 2010) has shown that in practice lenders engaged in widespread income-contingent renegotiations for households with negative equity prior to default which created implicit taxes that disincentivized labor supply. Consistent with a role played by household debt overhang I find that 2nd (lower paying) incomes respond more aggressively to

¹According to First American CoreLogic as of June 30, 2009.

negative equity, as would be expected in the presence of an implicit tax. I also find that the response is amplified in regions where mortgages are modified at a higher rate, even controlling for delinquency and foreclosure rates in those regions. One reason for regional variation in mortgage modification rates is state-level differences in the costs of foreclosure driven by judicial foreclosure requirements. Taking advantage of this I compare MSAs just across state border laws with different judicial foreclosure requirements, which discontinuously alter mortgage modification rates, and find effects are concentrated in states with more modification rates, driven by judicial foreclosure laws. Despite the potential economic importance of such a mechanism in policy discussions, to the best of my knowledge, this is the first paper to establish empirical evidence of the role mortgage debt overhang may have played in reducing household labor supply following the crisis.

Empirical identification of the effect of household debt overhang on labor supply faces a number of challenges which I address in this paper. First of all, few datasets have comprehensive household-level panel information on income, assets and liabilities. The few databases that do, such as the American Housing Survey (AHS), tend to be surveys that suffer from self-reporting biases and small sample sizes that confound clean identification². Even with appropriate data, simple regressions of labor income on negative home equity are unlikely to provide causal interpretation. A number of omitted variables drive both house prices and labor income (ex. local labor demand shocks) and reverse causality could be problematic since wealthier households are likely to invest more in home improvements.

² For example, Cunningham and Reed (2012) use AHS data, but only have 652 household-year observations over the course of 9 years with negative equity, which is a very limited sample for something as noisy as self-reported household equity and labor income.

In this paper I overcome these challenges by utilizing a new transaction-level dataset with comprehensive information on assets, liabilities, and deposits for all customers of a major U.S. financial institution from 2010-2014, referred to hereafter as *MyBank*, and an empirical methodology based on variation in the timing of home purchases. The transaction-level deposit information allows me to generate accurate high frequency measures of household income, while the data on assets and liabilities lets me determine which households have negative home equity. Since I observe actual deposits rather than reported values any estimated effects represent actual changes in deposit behavior rather than changes in household reporting in response to eligibility criteria³. I then use information on the timing of home purchase, relative to households in the same region, as an instrumental variable for the probability a household has negative home equity. In this empirical strategy households are exposed to identical time-varying local house price shocks, but differ in their home equity based on when they happened to purchase their home.

Since variation in the timing of home purchases is not randomly assigned I address concerns that omitted variables could be related to the timing of purchase and future income in a way that violates the exclusion restriction of the instrumental variables methodology. First I show that for low levels of expected loan-to-value, house price shocks have little effect, but as the probability of having negative equity rises, labor supply falls, consistent with an explanation driven by negative home equity. I also show that the results are robust to including household fixed effects, controlling for national cohort trends, and including a number of time-varying non-parametric household-level controls for household characteristics that could be related to local demand shock sensitivity. There could still be a concern that even within a region the timing of purchase

³ Chetty et al. (2013) have shown that in the context of household response to the EITC individuals manipulate self-employment reported income.

could be related to future house price movements and income shocks in an unobservable way. To reduce even that concern I instrument for negative equity using the age of student loans as a proxy for life-event driven home purchases and find that results are robust to this specification. This alleviates concerns that omitted variables such as industry choice drive both local demand sensitivity and the timing of home purchases.

One final concern I address is that households with *MyBank* mortgages and negative equity could be systematically hiding income from the institution they owe money. Since I measure only deposit inflows at *MyBank*, households who also have mortgages at *MyBank* could be closing accounts or reducing payroll inflows at that institution in order to appear less able to pay and receive more assistance. To partially alleviate this concern throughout my analysis I use multiple restrictions to be sure households in the panel have active retail accounts, taking advantage of the inflow and level information I have for all retail accounts at *MyBank*. Results are robust to all choices of filter and measures of income. I also rerun the analysis for households with a *MyBank* retail and credit card account, but have a mortgage where *MyBank* does not own or service the mortgage. In this case the household has no incentive to hide deposits and I find that negative equity still reduces income. Overall these results are consistent with income shrouding playing little role in the observed decline in deposits, so that results represent actual declines in overall household deposits. This may not be that surprising since virtually all income-contingent loss mitigation programs require documentation of income, which would include income deposited at any institution.

I. Literature Review

These results complement a recent body of work that investigates how households respond to excess liabilities. A number of recent papers have looked

at how indebtedness affects entrepreneurial activity (Adelino, Schoar, and Severino 2015 and Schmalz, Sraer, and Thesmar 2017), innovation and effort (Bernstein, McQuade, and Townsend 2017)⁴, employment opportunities among impoverished households (Bos et al. 2015)⁵, job search (Brown and Matsa 2017) and labor income among bankrupt households (Dobbie and Song 2015a). Melzer (2015) has also shown that households with negative home equity reduce investments in their house, since they anticipate no longer being residual claimants. Mayer et al. (2014) found that households were aware of the announcement of a large scale mortgage modification program by Countrywide and responded by falling delinquent, despite the ability to pay. Taken together these results suggest that a significant number of households are aware of their home equity and loss mitigation programs, and are willing to respond strategically via their home investment and mortgage payment decisions⁶. This paper contributes to this literature by showing that households also reduce their labor supply in response to the incentives provided by negative home equity and mortgage assistance programs.

This paper also fits within a broader literature analyzing the relationships between household liabilities, assets, consumption, and labor decisions. This includes a broad and growing literature trying to understand how negative home equity interacts with labor mobility in the U.S. and abroad (Fredrick et al. (2014),

⁴ Bernstein, McQuade, and Townsend 2017 find that workers whose house value declines innovate less. These results are consistent with reduced risk taking caused by a wealth effect, but also reduced provision of effort caused by negative home equity. This reduction in effort would be consistent with the predictions of the household debt overhang channel presented in this paper since these households would retain less of any financial gains from innovation because of the income-contingent nature of mortgage renegotiations.

⁵ The paper focuses on sample of households who were delinquent on a loan from a pawnshop within the last two years. Not surprisingly this sample population has very low income. Only 43% are employed and only 6% are homeowners. Credit constraints that prevent this population from finding employment, such as being unable to use a credit card to buy a suit, seem unlikely to extend to the average U.S. homeowner.

⁶ Even though the authors are unable to investigate the effects on income of the announcement of the countrywide program it is worth noting that settlement had debt-to-income targets of 34% for at least 5 years based on the previous 1 year of income, which like HAMP imply marginal tax rates in excess of 100%. A household willing to stop paying their mortgage and forgo an employment opportunity would be eligible for more than 100% of the forgone income in reduced monthly payments once they received a modification.

Cohen-Cole et al. (2015), Demyanyk et al. (2013), Donovan et al. (2011), Goetz (2013), Modestino and Dennett (2013), Mumford and Schultz (2014), Schulhofer-Wohl (2012), Bernstein and Struyven (2017))⁷, the effect of contract modifications including large scale loan modifications programs (Agarwal et al. (2010), Agarwal et al. (2012), Calomiris et al. (2011), Chang and Weizheng (2013), Collins and Urban (2015), Dobbie and Song (2015a), Dobbie and Song (2015b), Goodman et al. (2011), Goodman et al. (2012), Goodman and Woluchem (2014), Lucas et al. (2011), Mayer et al. (2014), McCoy (2013), Mulligan (2009), Schmeiser and Gross (2014), Gerardi and Li (2010)), and how liabilities alter household consumption and investment decisions (Schmalz et al. (2017), Baker (2015), Bhutta et al. (2010), Adelino et al. (2015), Cunningham and Reed (2013), Foote et al. (2008), Fuster and Willen (2013), Gerardi et al. (2013), Guiso et al. (2013), Melzer (2015) Sodini et al. (2016)). This paper also builds on a substantial literature estimating labor supply elasticities and the effects of implicit taxes (Chetty (2008), Chetty, Friedman, Olsen, and Pistaferri (2011), Chetty (2012), Jacob and Ludwig (2012), Chetty, Friedman, and Saez (2013), Low and Pistaferri (2015), Card, Johnston, Leung, Mas, and Pei (2016), Blundell, Costa Dias, Meghir, and Shaw (2016), Blundell, Pistaferri, and Saporta-Eksten (2016).

II. Mortgage Modifications and Household Debt Overhang

For highly levered firms a reduction in firm wealth reduces the marginal incentives for investment in positive net present value projects because the benefits accrue disproportionately to existing debt holders (Myers 1977). Highly

⁷ In these settings households are financially constrained by negative equity which prevents them from moving, also known as “housing lock”. Due to the effectively non-recourse nature of mortgages in the U.S. the effect of housing lock on mobility is unclear and empirical evidence has historically been divided, though more recent evidence is suggestive an effect on job search. Modestino and Dennett (2013) also point out that while non-pecuniary costs of immobility could be large, very few households in a given year have to move for employment, so the effect on aggregate labor supply is unlikely to be much larger than tenths of a percent, and certainly not the 2.3%-6.3% observed in this paper.

levered households face a similar problem when deciding to invest in the effort needed to earn labor income. If a portion of any marginal income earned by an indebted household is transferred to a lender via increased liability repayment, then this transfer to debt holders acts just like an implicit tax that incentivizes households to reduce their labor supply (Mulligan 2008, 2009, and 2010, Herkenhoff and Ohanian 2011, Donaldson et al. 2014).

While in practice income-contingent repayment for foreclosed properties in deficiency judgments are rare (Ghent and Kudlyak 2011), income contingent mortgage modifications were ubiquitous following the crisis (Goodman et al. 2011) and likely provide a major channel through which household debt overhang problems occur. In response to the substantial rise in mortgage delinquencies during the crisis, lenders engaged in large scale mortgage modification programs to help distressed borrowers. In fact from January 2008-May 2011 51% of all non-performing or re-performing subprime mortgages received a mortgage modification (Goodman et al. 2011)⁸. While these modifications may have been optimal collection strategies by lenders they may have also provided perverse labor supply incentives. Mulligan (2009) has shown that in theory and in practice lenders are more likely to engage in loss-mitigation actions for delinquent borrowers if they demonstrate a reduced ability to pay their liabilities. These income-contingent loss mitigations result in implicit marginal tax rates with strong moral hazard incentives for households to reduce labor supply. In the case of the majority of public mortgage modification programs debt-to-income targets create implied marginal tax rates in excess of 100% for households with negative equity, which as noted by Mulligan (2009) “is significant even from a macroeconomic perspective” and likely to “produce distortions that are large enough to be visible in the national employment data”.

⁸ For Prime, Alt A, and Option ARM, the modification rates were 23%, 31%, and 29% respectively.

These income-contingent loss mitigations mean that for many households with negative equity the majority of benefits from additional time and effort invested in employment income accrue to the debt holders rather than the household. For example, if an average negative home equity household with \$4,000/month in gross income and \$1,500 in monthly mortgage payments was seeking a mortgage modification via the Home Affordable Modification Program (HAMP) and worked to earn an extra \$500/month in income not only would all of the additional \$500/month in income accrue to the lender, the household would actually end up losing at least \$3,271 over the next 5 years despite the additional time/effort⁹. Just like in the classic corporate debt overhang problem faced by firms “the gain in the market value of debt acts like a tax on new investment [and] if that tax is high enough, managers may try to shrink the firm” (Myers 2001), where in the case of this household debt overhang problem the borrower reduces the “firm” by reducing their labor supply. This could mean that a fall in housing wealth, which via a wealth effect would normally suggest a rise (weakly) in household labor supply, could actually cause a reduction in labor supply via a substitution effect coming from the implicit marginal tax of the income-contingent loss mitigation by the lender.

III. Data Description and Validation

The majority of my data comes from a major U.S. financial institution but I also merge in zip-code level income from the Internal Revenue Service (IRS) to validate my income measures and state-level judicial foreclosure law information. The data provider for this project is a major U.S. financial institution, who I refer to as *MyBank*, with transaction-level client account information on more than 1/4th of all U.S. households over the 5 years from 2010-2014¹⁰. For the purposes

⁹ Calculations based on checkmynpv.com.

¹⁰ According to census.gov from 2009-2013 there were about 116 million U.S. households and *MyBank* has client accounts covering more than 31 million households (see Table A1 for details), which would be about 27% of all U.S. households.

of this project I focus on households with sufficient *MyBank* relationships to estimate income and mortgage information and analyze income decisions at a monthly household level. Income is estimated using retail account deposit information and mortgage information is either derived from credit bureau data (only available for households w/ *MyBank* credit card accounts) or *MyBank* mortgage account information. In appendix A I detail how combining household information from multiple *MyBank* accounts alters the sample size.

For each mortgage account I have detailed information on the mortgage type (ex. fixed rate 30 year), characteristics at origination including the date, reported income, credit score, interest rate, appraised loan-to-value, and ongoing monthly mortgage performance, characteristics, and actions, including delinquency status, current loan-to-value updated using internal LPS MSA-level HPI data, any loss mitigation actions taken, such as mortgage modifications, and current interest rates. Perhaps not surprisingly given the substantial coverage of this data provider, in Figure B2 in the appendix I show that the time series of delinquency rates for *MyBank* mortgage data matches closely with the levels and trends seen in national Federal Reserve economic mortgage data over the past 5 years.

By a substantial margin the largest population of households with a *MyBank* relationship are credit card customers. This should be expected since households very often only have one mortgage lender, but will have multiple credit cards. For each credit card account and month *MyBank* pulls credit bureau data on the associated customer liabilities. For the purposes of this paper this monthly frequency credit bureau data is the only information used from the credit card accounts. The credit bureau data includes comprehensive data on all

The coverage is lower when looking at individuals, which is likely because dependents are unlikely to have separate *MyBank* accounts (ex. children) and some households with multiple adults still may choose to list only one person in the account information.

customer liabilities across all lenders including mortgages, auto-loans, student loans, home equity lines of credit, credit cards, and installment credit as well as monthly updated credit scores. For each credit category the dataset includes information on the balance, monthly payments, and initial balance¹¹.

Retail accounts include any checking or savings accounts. The raw data includes every single transaction into these accounts (inflows and outflows) but to protect privacy include only the day a transaction occurred, the amount of the transaction, and very general transaction category types (ex. “ACH direct deposit”). The dataset includes billions of transactions over the period 2010-2014, but since my goal is to measure income I focus on the subset of transactions labeled as deposits, which include direct deposits, physical deposits including at the teller and ATM, and other deposit types including mobile RDC deposits. Since some of these accounts are not being used to deposit the majority of income I restrict my analysis to households with active accounts¹² that appear to contain the majority of their income¹³.

To explore the validity of using deposits as an income measure I confirm the validity of my income measure by comparing the average annual income based on my deposit data at a zip code-level with those reported by the IRS Statistics of Income (SOI)¹⁴ over the period 2010-2013. In Figure B1 you can see

¹¹ Maturities and interest rates on these liabilities are estimated and validated for the subset of data where both are available. In particular, given the panel nature of the data I am able to observe total monthly payments in addition to changes in the outstanding balance for each account month over month. Assuming a fixed interest rate, maturity, and standard amortization schedule I numerically estimate what would be the implied interest rate and maturity from a selection of discrete interest rates and maturities that exist in the data for each set of back-to-back months. If less than 75% of estimated interest rates and maturities for given product do not match or I have less than 20 observed estimates I do not include them in the sample. Even with sufficient information these could have floating rates, non-standard amortization schedules, or unusual pre-payment behavior which would confound clean identification of the underlying maturities and rates. More information on the internal quality of the method are available upon request.

¹² A household is defined to have “active” accounts if across all accounts in a given month they deposit at least \$100 or have \$200 in financial assets.

¹³ To be included in the panel all households must have at least 12 months with deposits across all accounts $\geq \$100$ & $\leq \$25k$, a mean and median level of deposits across all accounts $\geq \$500$ & $\leq \$25k$.

¹⁴ For the purposes of income validation, I utilize publicly available zip-code level income data from the IRS (Internal Revenue Service) Statistics of Income for 2010-2013. This data is based on administrative records of individual income tax returns (Forms 1040) from the IRS Individual Master File (IMF) system. More details about IRS SOI income data are available online at www.irs.gov.

a very strong correlation between these measures of income. Regardless of the type of income measure used and the subsample explored I find that zip code level correlations between my measure and the IRS SOI are very high and range from 0.736 all the way up to 0.911. The fact that the relationship is so strong between these two measures and one measure does not appear to be systematically higher suggests that for the subset of households analyzed deposits represent an effective measure of household income. I also extract households receiving social security or disability checks. After excluding regularly schedule job-related deposits, I assign any remaining direct deposits that are paid on either the 3rd of each month, or the 2nd, 3rd or 4th Wednesday of each month as social security-related. According to the Social Security Administration the mean monthly benefit for a beneficiary is \$1,223/month which matches closely with the mean of \$1,268/month I find per social security recipient in my sample. This validates not only the data overall, but also this method of extracting social security payments.

For the majority of my analysis I focus on households with retail deposits that let me measure income, and mortgages at *MyBank* that let me see their level of home equity or about 200k households in the final sample representing approximately 7.8 million household-month observations. For most of my analysis I focus on households with income at origination, loan origination date, and additional information which restricts that to approximately 5.4 million household-month observations. I also consider households with *MyBank* retail and credit card accounts and mortgages with any lender as robustness check, which increases the sample to about 20.1 million household-month observations. For more details on the data merging see Table A1 in the appendix.

I analyze a broad range of characteristics for each sub-sample of *MyBank* in Table 1 and in more detail in Table B1 in the appendix. From the tables we can see that the median household income for households with mortgages is about \$5-

6k/month and as expected the majority of household liabilities are mortgage related. The median level of income, non-housing financial assets, mortgage leverage, and mortgage interest rates are similar to self-reported information collected by the Survey of Consumer Finance (SCF) for households with at least \$1,000 in active mortgage balance in 2010 consistent with the representative nature of the *MyBank* national coverage and lends credibility to the external validity of the conclusions of this paper. For more details on this comparison see Table B2 in the appendix.

The *MyBank* mortgage data includes information on reported income at origination which provides a nice opportunity to test the validity of the cross-lines of business data matches as well as providing another check of the quality of my deposit based income measure. In Figure B1 I plot the cumulative distribution function of income at origination and income based on deposits for a match sample of individual households who originated a mortgage in the same year when sufficient deposit information is available to estimate income. These distributions appear remarkably similar and the individual income correlations range from 0.378 to 0.449 depending on the measure of deposit income used, all of which lend substantial credibility to the internal matches across *MyBank* lines of business as well as validating my income measure across the income distribution.

As noted by Mian et al. (2015), states that don't require judicial procedures for mortgage lenders to foreclose on delinquent borrowers are twice as likely to foreclose. The increased ease and likelihood of foreclosure reduces the likelihood that non-performing mortgages will receive a modification. For example, the documentation for the net present value tests for mortgage modifications under HAMP includes "state-level foreclosure timelines" and "state-level average foreclosure costs" as major determinants of whether or not a mortgage modification should be undertaken. To explore this source of variation I

merge in state-level judicial foreclosure requirements based on RealtyTrac's website, just as was carried out in Mian et al. (2015).

IV. Empirical Methodology

To understand the effect of negative household equity on labor supply I run an instrumental variables regression using variation in the likelihood of negative equity based on the timing of home purchase relative to households living in the same region at the same time. To build intuition for the instrumental variables approach though I start by running the following regression

$$y_{icrt} = \alpha_i + \gamma_{rt} + \sum_k \delta_{1k} \cdot 1_{\{l_k \leq LTV_{it} \leq h_k\}} + X'_{it}\beta + \epsilon_{icrt} \quad (1)$$

where for household i in month t in region r that originated their mortgage on date c , this regresses household income, y_{icrt} , on a dummy variables which equals 1 only if the households loan-to-value ratio, LTV_{it} is greater than l_k and less than h_k for k loan-to-value buckets, region x time fixed effects, household-level fixed effects, and a number of time-varying household level controls, X'_{it} . The problem with a naïve regression of income on home equity is that reverse causality or omitted variables are not only possible, but are likely to prevent confidence in any causal interpretation of the effect of negative equity on labor supply. For example, time varying local demand shocks and initial credit quality could affect both income and home equity and households with higher income likely invest more in home maintenance. Since I compute changes in house prices at region level, the inclusion of region x time fixed effects precludes the possibility that results are driven by variation in local demand shocks or individual variation in home investment. I also include multiple loan-to-value indicator buckets to see if, as would be predicted by household debt overhang, declines in income occur only for high loan-to-value ratios. In this specification I also include household fixed effects to rule out any time invariant omitted variables, as well as time-varying

household-level controls such as the amount of mortgage pre-payment as well as non-linear controls for credit score, origination home equity, and origination income interacted with time fixed effects.

Despite the inclusion of all these controls time-varying household level variation in LTV still has the potential to confound casual interpretation. In equation 2 I make this more transparent by decomposing the current household's LTV into three distinct components; (1) house prices changes, (2) changes in the balance of the mortgage, and (3) origination LTV.

$$LTV_{it} \equiv \frac{1}{\% \Delta HP_{rct}} \times \% \Delta Loan_{it} \times LTV_{ic} \quad (2)$$

Since households with improved income are more likely to prepay their mortgage, reducing the LTV, prepayment poses an empirical challenge for identification. To circumvent this rather than using actual changes in loan amount, I compute what the loan reduction would be if the mortgage was a 30-year (360 months = T) fixed rate loan paying the median national monthly mortgage rate, r (I use 6.75% based on my sample statistics).

$$\% \Delta SynthLoan_{ct} \equiv - \frac{(1+r)^{t-c} - 1}{(1+r)^T - 1} \quad (3)$$

The resulting formula in equation (3) varies across mortgages based on the age of the loan, but no longer depends on any other source of household-specific variation. An additional concern is that origination LTV could be a function of household specific characteristics, such as income or credit quality. Since I include household-level fixed effects in specification (1), time-invariant factors, like LTV at origination, are only a concern when interacted with a time-varying factor, as is the case here. In particular, if high LTV at origination individuals are more sensitive to local demand shocks then this could be driving any simultaneous movement in income and household equity, rather than labor supply. To alleviate this concern I use the median national LTV at origination for each

cohort for all households. Combining these I get the synthetic LTV, or $SLTV$, which only varies at the cohort-region-time level, and, controlling for all previously mentioned fixed effects, provides a plausible instrument for the probability of household having negative equity:

$$SLTV_{rct} \equiv LTV_c \times \frac{1}{\% \Delta HPI_{rct}} \times \% \Delta SynthLoan_{ct} \quad (4)$$

Variation in SLTV, after including all controls in equation (1), will be driven almost entirely by the timing of house purchase within a given region.

Households that bought homes prior to relative local house price declines will have higher SLTVs relative to those who bought immediately afterward.

To formalize the instrumental variable approach define I run a 2SLS regression where the 1st stage is

$$U_{it} = \alpha_i + \gamma_{rt} + \phi_{ct} + \delta_1 \cdot 1_{\{SLTV_{rct} \geq 100\}} + X'_{it} \beta + \epsilon_{icrt} \quad (6)$$

,where I defined a household who has negative home equity (aka underwater) as $U_{it} \equiv 1_{\{LTV_{it} \geq 100\}}$, and the 2nd stage is¹⁵

$$y_{icrt} = \alpha_i + \gamma_{rt} + \phi_{ct} + \delta_2 \cdot \hat{U}_{it} + X'_{it} \beta + \epsilon_{icrt} \quad (7)$$

The necessary assumption for the exclusion restriction is that after controlling for all fixed effects the synthetic LTV only affects income via the probability the house has negative home equity. To extent that all remaining variation in SLTV after all controls is driven by the timing of home purchases the exclusion restriction requires that the timing of home purchases is unrelated to other factors that could alter future income changes. To make this clear as a robustness check I also replace the 1st stage above with one that only includes house price changes at a region-cohort-time level explicitly.

¹⁵ I run this using the 1st stage as a linear probability model using negative SLTV as the instrumental variable. For robustness I also show results using multiple loan-to-value bucket indicators in the 1st stage, but not probit or linear-linear models. As noted by many papers (ex. Greene 2004) probit estimates are inconsistent in a fixed effect panel regression as are purely linear models when the underlying treatment effect varies non-linearly.

This still leaves one possible confounding factor; the timing of house purchases within a region could violate the exclusion restriction. For example, if house price purchases by households with income more sensitive to local demand shocks could predict future house price declines then this could be potentially problematic. To address this concern I focus on life-event driven moves based on the time since a household attended college. In particular, for each household rather than using the region-cohort-time percent change in house price I instead use the expected change in house price at the region-college attendance year-time as a proxy for the house price change.

V. Results

A. Negative Home Equity and Household Labor Supply

In this section I analyze the results of using variation in the timing of house purchases as a plausibly exogenous source of variation in the probability of having negative home equity among households living in the same region at the same time. In Table B3 in the appendix in column 1 I regress the % change in income, normalized by income reported at the time of mortgage origination, on indicators for varying loan-to-value ratio ranges, while including MSA x time fixed effects, household-level timing varying prepayment controls, income at origination, and 10% indicator buckets for original loan-to-value interacted with time fixed effects. Consistent with negative equity reducing labor supply I find that for low values of loan-to-value buckets income does not fall, but for high LTVs income falls by 4-5%. One potential concern is that income at origination and the additional other household time invariant controls may not capture all differences in characteristics across cohorts that could later reduce income via omitted variables. To address that concern in column 2 I rerun the analysis using household fixed effects. Though there is a small increase in the income reduction for a lower tier of loan-to-value ratios, for all high loan-to-value ratios results are

largely unchanged. The non-linear nature of the effect of loan-to-value ratio on changes in income is illustrated clearly in Figure 1. In this figure the x-axis are indicator dummies for each household-month that appears in a given 10% LTV bucket and the right hand side are the co-efficients from the regression run I just described for column 2. The only difference, besides more granular buckets, is that I normalize the fixed effect so buckets less than 100% sum to zero, allowing us to cleanly observe any changes that occur for high loan-to-value buckets. What we see is that for low loan-to-value ratios changes in loan-to-value do not have significant effects on labor income, but for high values, especially those above 100% LTV we see a large and consistent reduction in income. These results are consistent with household debt overhang causing a reduction in labor supply¹⁶. If we were concerned that variation in moving date is generally correlated with sensitivity to local demand shocks we would expect differences in income changes even for low loan-to-value buckets. Restricting the analysis to only direct deposits on the left hand side in column 3 yields almost identical results, lending credibility to the fact that changes in deposits are being caused by a reduction in wages rather than some other form of account inflows¹⁷.

As was mentioned previously there could still be a concern with the above procedure that time-varying household specific factors, including income, could influence the loan-to-value ratio. To address this concern in Table 2 I set a dummy variable equal to 1 if the synthetic loan-to-value ratio, which is not based any household specific time varying factors, is greater than 100%. In column 1 I run a reduced form regression using the negative equity synthetic LTV as an instrument,

¹⁶ Note that for lenders the pertinent loan-to-value ratio would be the value after sale, including all costs. Since these house prices are computed at a region level and do not account for the costs of execution we would expect some reduction in income even for households with observed loan-to-value ratios just below 100%. Typically closing costs, including agent commissions, tend to be 6%-10% of house value (source: realtor.com).

¹⁷ The fact that similar effects are seen using direct deposits suggests that though there is compelling evidence that reductions in home equity can dampen entrepreneurship (Adelino, Schoar, and Severino 2015 and Schmalz, Sraer, and Thesmar 2017), it is unlikely these are the driving force behind the overall reduction in labor supply observed in this setting, even if it may be important for the composition of job types and income among a subset of the population.

after controlling for MSA x time and household fixed effects, and I find that it is associated with a statistically significant reduction in household labor income. To quantify the size of this effect and the validity of the IV I run a formal 1st stage in column 2 and find that a negative SLTV is associated with a 36.8% higher chance of a household having negative equity, after controlling for MSA x time and household fixed effects, and reveals that this is a strong instrument. The formal result of this IV is shown in column 3 and shows that estimated average effect of negative equity is a 3.63% reduction in household income. When re-running the analysis using raw \$ deposits per month instead of normalizing by origination income I find that it reduces income by -\$366/month or about 4% of mean monthly income in my sample.

In columns 5-6 I show the results are robust to the choice of instrument. In particular, in columns 5 I use a non-linear 1st stage based on 10% SLTV buckets and find that income falls 2.34%. As noted previously, you may still be concerned that even the SLTV could be providing some variation in current LTV not driven solely by the timing of moving. To alleviate this concern I use 10% buckets for MSA level house price changes since mortgage origination as an instrument, after controlling for MSA x time and household fixed effects. The reduced form of this IV regression is shown in Figure 2. Just as was the case with loan-to-value, for low or positive differences house prices based on the timing of moving relative to households in the same region at the same time there is no change in income, but when house prices are significantly lower income falls. Since I am controlling for MSA x time fixed effects and computing changes in house price since origination at an MSA level the only source of variation here is based on the timing of home purchase relative to home owners in the same region at the same time. I run this IV formally in column 6 and find that as expected negative equity is associated with a decline in household income.

Overall these results are consistent with negative home equity causing an average labor income decline of 2.3%-6.3%. With some additional assumptions I can estimate the labor supply elasticity with respect to the implicit tax rate of mortgage modifications. In my mortgage data households with negative equity are 21 percentage points more likely to receive mortgage modifications than those without negative equity. From Mulligan (2009) we know that national mortgage modification programs create a substantial implicit tax, but lost income occurs immediately while lost benefits occur over the following 5 years. We know that total benefits over those 5 years are 1.2-1.5 times larger than the loss in income, so an implicit present value tax rate of 100% is consistent with reasonable discount rate benchmarks. Combining these we can say that the average household with negative equity faces an expected implicit marginal tax rate of 21% and since they reduce their labor supply by 2.34%-6.34% this implies an elasticity of 0.11-0.30. These estimates are lower than the elasticities of 0.94 estimated by Dobbie and Song (2015b) among bankrupt households, but are similar to the estimates of the Hicksian elasticity of labor supply in the microeconomic literature, which tend to be near 0.25 (Chetty 2012).

Using the estimated labor supply declines for negative equity we can also get some estimates of the potential macro-economic effects. If the average unemployed household on average earns half of their employed level of income and all changes in labor supply occur via the extensive margin then a 2.3%-6.3% reduction in labor income is consistent with a 4.6%-12.6% rise in unemployment among negative equity households. CoreLogic estimates that approximately 15 million households had negative equity following the crisis. Combining these estimates and aggregating the partial equilibrium results suggest a 0.69-1.89 million decline in job-equivalent labor supply because of household debt overhang. From the peak of 2008 to the trough in 2010 non-farm payrolls fell by about 8.6 million jobs, so the estimated decline from household debt overhang

would be 8%-21% the size of the total general equilibrium employment decline following the crisis. Since these are just the linear aggregations of partial equilibrium estimates these give us some idea that the magnitudes are unlikely to be large enough to explain most of the observed labor participation decline, but have the potential to exacerbate existing employment declines, especially in regions with concentrations of negative home equity¹⁸.

B. Robustness Checks

One potential concern with these results is that the timing of purchase might be correlated with factors related to future house price changes and labor income declines, which would violate the exclusion restriction of the instrumental variable regression used. I attempt to address these concerns in Table 3. In columns 1 and 2 I rerun the analysis in columns 3 and 4 of Table 2, but now also include cohort x time fixed effects. If the concern is that national trends in the timing of home purchases around the time of the crisis could be related to labor demand shock sensitivity this should capture any variation coming from national cohort effects. The resulting source of variation exploits variation across cohorts and regions with varying time series house price patterns over the same time period. I find that effects are essentially unchanged by the inclusion of cohort x time fixed effects where estimated declines in labor income due to negative home equity are 3.47% and \$298/month. In column 3 I still include purchase cohort x time fixed effects, but also a large range of non-parametric household-specific time varying controls that might be expected to be correlated with labor demand sensitivity. These include declines for origination income and property value,

¹⁸ The actual total amount of reduced labor participation following the crisis that can be explained by household debt overhang will depend critically on labor demand and in particular the stickiness of wages. This exercise is meant to provide some benchmark for the potential aggregate partial equilibrium shocks generated by this channel, but are by no means intended as an estimate of the actual general macroeconomic equilibrium effects. As is noted by Chetty, Friedman, Olsen, and Pistaferri (2011), among others, macroeconomic estimated labor supply elasticities tend to exceed microeconomic estimates and typically cannot be easily recovered without the benefit of an underlying structural model.

mortgage original interest rate by percentage buckets, and original credit score in bins of 50 all interacted with time fixed effects. These results show a 4.94% decline in household income, again consistent with overall results.

Even with all these controls, there is still the potential I am missing some omitted variable which varies within region relative to national trends, but that predicts both future relative house price performance in a region and local demand sensitivity. One possible story could be the industries that are related to real estate, such as construction, could perform well in regions when house prices rise, encouraging employees in those industries to purchase properties just before local house price declines. Since workers incomes are more exposed to house price declines this could lead to a violation of the exclusion restriction. To address even this concern I use the time since a household attended college, as proxied by the average origination date of all student debt¹⁹, as an instrument for the likelihood of a household having negative equity. The idea is that the timing of home purchases in this case is life-event driven, such as moving after graduating college, rather than something like occupational choice. Consistent with all the previous results I find in column 4 that this IV regression estimates that negative equity is associated with a 3.78% reduction in household income. This is despite a reduced sample size and comparing similar households, since they still have outstanding student debt. Another possible concern is that workers who entered the labor market more recently would be the ones more likely to be laid off. To address this in column 5 I use this same sample of households with information on approximate college graduation date, but now include fixed effects for MSA x time x college graduation year. While not having age fixed effects is a limitation this allows me to control for the duration of time the household head has been in

¹⁹ For a small subsample of households with credit cards I have information on when they graduated college. This sample is too small to use as an instrument, but has provided credibility that as would be expected, average origination date of student loans is highly correlated with the timing of college graduation. Validation results are available upon request.

the local labor market, which is likely to be correlated with age and more likely to be related to job duration, and rely on the remaining variation. Even with this more stringent level of controls I find a statistically significant decline in income, consistent with previous estimates. Then finally in column 6 I address concerns that the timing of home purchase and location even within a given MSA may have been correlated in a way that exposed these households to larger local demand shocks for the same MSA-level shock. In this specification I include zip code x time fixed effects, instead of MSA x time fixed effects, and again I find similar declines in labor supply, suggesting selection within MSA is not driving the observed results.

One additional concern with all the analysis up to this point could be that I measure deposits at only one institution and in particular I use deposits from the same institution that is their mortgage lender. If households hide income from their lender when they have negative equity this could mean that the reduction in deposits seen for households with negative equity is actually just movement of deposits to another institution rather than an actual decline in overall deposits from income. With this concern in mind throughout my analysis I use multiple restrictions to be sure households in the panel have active retail accounts, taking advantage of the inflow and level information I have for all deposit accounts at *MyBank* and results are robust to all choices of filter and measures of income. To be even more careful though in Table B7 in the appendix I rerun my analysis focusing on *MyBank* retail customers with a mortgage from another lender. Since I no longer have detailed mortgage information I use the zip code households enter in their retail accounts²⁰ as a proxy for the MSA the property is located in and information from the credit bureau data on mortgage origination dates. I then utilize the same synthetic LTV computed in the previous analysis based on those

²⁰ For households with multiple zip code I use the zip code of the largest account and the date closest to the origination of the most recently originated mortgage.

households with *MyBank* mortgages, which varies only at the region-time-cohort level. Note that in this case these are reduced form regressions since current LTV is not available in credit bureau data to run the 1st stage. This method of computing the synthetic LTV is likely to reduce the power of the regression, but the reduced form regression still finds that negative SLTV is associated with lower deposits, after including all region x time, cohort x time, and household fixed effects. The result holds when analyzing households with mortgages at any lender or for the subset of households where *MyBank* is not a servicer or owner of the mortgage. Overall these results suggest that hiding income is unlikely to explain the reduction in monthly deposit inflows seen for households with negative equity.

In Tables B4-B6 in the appendix I show that these results are also robust to the choice of measurement of changes in income and liabilities, clustering of standard errors, definition of the household, and are not driven by costs caused by delinquency. In columns 1-3 of Table B4 I show that results are largely unchanged when I use current deposits divided by mean deposits over my whole sample, rather than the reported income at origination, the log of deposits, or only direct deposits. In column 4 I show that results are still significant when clustering at the MSA instead of MSA-month level and in column 5 results hold when using *MyBank*'s internal definition of a household instead of my own proxy²¹. In Table B5 I rerun the analysis among the subset of households that also have a *MyBank* credit card account, which allows me to observe all their credit bureau liabilities. In this specification I show that results are robust to using a measure of negative equity based on all liabilities not just those associated with the primary mortgage balance. Since households with negative home equity are more likely to fall

²¹ The definition I use throughout the paper assumes that any customers who are jointly liable on any liabilities or jointly listed in any retail deposit account together constitute a household. This measure is highly correlated with the internal measure of a household, but is more flexible since it allows for a definition based off joint use of accounts directly rather than self-reported definitions of family structure.

delinquent, if the costs of delinquency itself, such as explicit costs, stress, or employer background checks, affect income this could suggest that results are driven by increased delinquency itself. I show in Table B6 though that the results are significant even looking at only all households that are current on all mortgage payments and so don't face direct costs associated with delinquency.

C. Extensive vs. Intensive Margin

To understand potential drivers of the decline in labor supply for households with negative equity I investigate how households change their income. Do they alter their labor decisions via the extensive margin, such as labor market participation, or the intensive margin, such as altering hours worked at existing jobs? Unfortunately, since I do not observe occupational choice I cannot test this directly, what I can test is to what extent changes in income are driven by households making large employment decisions or a many households making marginal changes. In Table 4 I test this in columns 2 and 4 by excluding cases where income changes by more than 25% relative to either the income at origination or the mean income estimated in sample. I find that when excluding large employment decisions there is no longer statistically significant relationship between negative equity and labor supply. This suggests that small changes driven by say reduced ability to wage bargain with a monopsonist among households whose labor mobility is reduced by negative equity²² is less likely to provide an alternative explanation for the labor supply results shown in this paper. In columns 1 and 3 I show that these results are not driven by households systematically leaving the bank. I exclude only cases where households deposit \$0 into their accounts and results are still significant. It appears that households make large extensive margin changes in labor income, say by increasing search duration, but are also more likely to leave the labor market entirely. In particular,

²² See for example Cunningham and Reed (2012).

I show that households with negative home equity are more likely to receive social security or disability checks, which suggests that they are either more likely to retire or move onto disability and in doing so reduce their labor supply by reduced labor participation, rather than unemployment. I find increased deposits received for social security, despite the fact that overall deposits fall, so this result is unlikely to be driven by overall deposit trends.

D. Household Debt Overhang

While establishing the effect of negative home equity on household labor supply is important for understanding local macroeconomic effects of house price declines, policy implications are likely to depend critically on understanding channels driving the effect. Since results are shown using only direct deposits, are concentrated along the extensive margin, and are not driven by delinquent borrowers, there is likely to be a significant channel driving the results beyond wage bargaining, entrepreneurship, damaged credit scores, or anticipated wage garnishment. One plausible channel discussed in detail earlier is household debt overhang, since negative equity could encourage income-contingent renegotiations, which act like implicit taxes with a moral hazard problem that disincentivizes labor supply. As noted previously and is shown in Figure 3, negative equity dramatically raises the probability of mortgage modifications and in Figure 4 I show evidence that deposit inflows rise after mortgage modification terms are locked-in in an event study setting²³. I also show in Table 5 and appendix Table B8 that consistent with previous empirical evidence (Blundell, Costa Dias, Meghir, and Shaw 2016, Blundell, Pistaferri, and Saporta-Eksten 2016), labor supply elasticities are larger for 2nd sources of income within a household, suggestive of the potential for a role played by a channel acting like an

²³ Since the timing of mortgage modifications is not random and would likely occur during a period of duress estimates in this case are likely to be biased up and while consistent with overall findings are unlikely to provide plausibly accurate estimates of the true effect.

implicit tax²⁴. This is again suggestive of a connection between negative home equity, household debt overhang, and labor supply.

I formally test this suggestive evidence in Table 6 columns 1-3 by showing that the effect of synthetic negative equity on labor supply is larger in regions with higher mortgage modification rates, even controlling for the delinquency rate in those regions. Typically, it would be challenging to distinguish the effects of housing lock from debt overhang since both are driven by negative equity and can alter job search. In this case though, if the variation in treatment effects are really driven by the causal effect of modification rates it would be compelling evidence that housing debt overhang plays an important role beyond housing lock. Debt overhang would be stronger if modification rates are higher, while these mortgage renegotiations, such as short sales or increased home equity, would actually reduce the effect of housing lock.

One concern with this approach is that mortgage modification rates are not randomly assigned, so if controlling for DQ, they are more common in say states which allow for recourse, this would be problematic. For example, Brown and Matsa (2017) have shown evidence the job search appears to be hampered more by housing declines in recourse states, which would be consistent with a larger role played by housing lock in those states. To address this concern, I use the fact that time to delinquency, largely driven by variation in judicial foreclosure requirements are one of the most important components in the decision to modify a mortgage (hmpadmin.com). Mian et al. (2015) and Ghent (2012) convincingly argue that state foreclosure laws differ based on historical path dependent exogenous events and provide evidence of co-variate balance across these borders for a broad range of characteristics for states with and without judicial foreclosure requirements. In Figure 5A and Table B9 columns 1-3 in the appendix I show that

²⁴ The relatively large elasticity of labor supply estimated in this paper may also be consistent with Card et al. (2015) who find stronger extensive margin labor supply responses to unemployment insurance benefits in the crisis, than before it.

modification rates among seriously delinquent borrowers increase discontinuously in states with judicial foreclosure requirements, while in Figure 5B and Table B9 column 4 I show that modification rates actually fall in recourse states. Leveraging this discontinuously differential source of variation in Table 6 columns 4-5, I compare MSAs just across state borders with differing judicial foreclosure laws. I find that the effect of negative equity on household labor supply is larger for households in judicial foreclosure states, where modification rates are higher, even controlling for the recourse laws of the state. In column 6 I rerun the same analysis focusing on MSAs just across state borders with differing recourse laws and find a similar point estimate, but nothing statistically significant, providing additional evidence that my results are not driven by variation in recourse laws and subsequent variation in housing lock. This is not to say that housing lock does not have a significant effect on labor decisions. In this setting I am using a regression discontinuity combined with a reduced form instrumental variables approach which may just not be sensitive enough to observe these effects. There is also evidence that if housing lock reduces mobility in the U.S., like it does in the Netherlands, there are large number of significant non-pecuniary costs to housing lock (Bernstein and Struyven 2017). Rather it appears that independent of any costs associated with housing lock or other channels, household debt overhang appears to be an important driver of the relationship between negative home equity and household labor supply.

V. Conclusions

In this paper, I provide the first empirical evidence of the causal effect of negative home equity on household labor supply. I use a new comprehensive dataset with information on household-level liabilities, assets, and all deposit transactions for all customers of a major U.S. financial institution from 2010-2014 and variation in home equity based on the timing of home purchases among

households in the same region at the same time. I find that instrumented negative home equity causes an average reduction of 2.3%-6.3% in household labor income. I then explore the channels driving this result and find evidence for a new link, household debt overhang, between negative home equity and labor supply. Household debt overhang arises when income-contingent means-tested mortgage modifications act like implicit taxes, resulting in a moral hazard problem that causes labor supply disincentives. Consistent with households responding to an implicit tax I find that responses are larger for 2nd incomes within a household. I also show that responses are larger for MSAs on state borders, in states with judicial foreclosure requirements that have discontinuously higher mortgage modification rates.

These results shed new light on the role house price declines played in exacerbating employment declines following the crisis. Mian and Sufi (2012) have examined how house price shocks affect equilibrium employment via local labor demand, but this is the first paper to demonstrate the role house price declines played in labor markets via the supply channel. While identifying the aggregate general equilibrium response to home equity is beyond the scope of this paper, my results do suggest that it has a role to play in understanding how household balance sheets can exacerbate financial crises. While the overall relationship between negative home equity and labor supply is important in analyzing the sluggish recovery following the crisis, evidence of a role played by income-contingent renegotiation has additional important policy implications. In particular, evidence that household debt overhang effects household labor supply decisions, suggests that assistance programs should be designed taking into account the trade-off between more targeted assistance via income-contingency with the potential labor supply consequences.

Table I. Summary Statistics

This table includes simple summary statistics for *MyBank* data. To be included in the panel all households must have at least 12 months with deposits across all accounts $\geq \$100$ & $\leq \$50k$ and a mean and median level of deposits across all accounts $\geq \$500$ & $\leq \$25k$. For direct deposits the HH must have at least 12 months of direct deposits $\geq \$100$ & $\leq \$25k$, a mean and median level of direct deposits across all accounts $\geq \$500$ & $\leq \$25k$ and $\geq 75\%$ of all deposits must be via the direct deposit channel. All data winsorised at 99th percentile. This sample includes only households that have retail and mortgage accounts at *MyBank* from 2010-2014.

	Mean	Median	Std. Dev	# Obs (mil)	# HHs (mil)
A. Households w/ <i>MyBank</i> Retail & <i>MyBank</i> Mortgage 2010-2014

Is Fixed Rate	83.9%			7.835	0.200

Table II. Negative Equity and Labor Supply

This table shows the average change in household income associated with negative household home equity using variation in the timing of home purchase as an instrument for the probability of having negative equity. Column 1 regresses the % change in deposits, where the numerator is the monthly deposit inflows and the denominator is the households income at the time of mortgage origination, on a dummy which equals 1 if my synthetic loan to value ratio (SLTV) is greater than 100%, region x time fixed effects, and household fixed effects. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. Column 2 is the same as 1 but includes a dummy equal to 1 if a household's current loan to value is greater than 100%. This is the 1st stage estimate of the IV regression. In column 3 I present the results of using the IV in column 2 on the % change in deposits normalized by origination income. Column 4 is the same as 3 but includes raw monthly deposit inflows as the dependent variable, without any normalization. Column 5 is the same as 3 but uses dummies for SLTV 10% bandwidth buckets as an IV. Column 6 is the same as 5, but uses 10% buckets of MSA level house price changes since mortgage origination as non-linear IV. All standard errors clustered at the MSA x Cohort level.

	(1)	(2)	(3)	(4)	(5)	(6)

Table III. Controlling for Cohort Effects

This table shows the decline household income associated with negative household home equity using variation in the timing of home purchase as an instrument for the probability of having negative equity, is not driven by differential cohort sensitivity to local demand shocks. Column 1 regresses the % change in deposits, where the numerator is the monthly deposit inflows and the denominator is the households income at the time of mortgage origination, on an instrumented dummy equal to one if current mortgage loan to property value is greater than 100%, region x time fixed effects, household fixed effects, and purchase date cohort x time fixed effects. A dummy which equals 1 if my synthetic loan to value ratio (SLTV) measure is greater than 100% is used as an instrument for the likelihood that a household has negative home equity. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. Column 2 is the same as 3 but includes raw monthly deposit inflows as the dependent variable, without any normalization. Column 3 is the same as 1 but also includes time varying non-parametric household-level controls. These include deciles for origination income and property value, mortgage original interest rate by percentage buckets, and original credit score in bins of 50 all interacted with time fixed effects. Column 4 uses the time since a household attended college, as proxied by the average origination date of all student debt as an instrument for the likelihood of a household having negative equity. Column 5 restricts the sample to the same as column 4, but reruns the main specification and includes fixed effects for MSA x time x college graduation year. Column 6 is the same as the primary specification, but includes region x time fixed effects at the zip code level. All standard errors clustered at the MSA x Cohort level.

	(1)	(2)	(3)	(4)	(5)	(6)

Table IV. Extensive vs. Intensive Margin

This table explores the drivers of the negative effect of mortgage loan-to-value (LTV) on labor supply. Just as in the main specifications Column 1 regresses the % change in deposits, where the numerator is the monthly deposit inflows and the denominator is the households income at the time of mortgage origination, on an instrumented dummy equal to one if current mortgage loan to home value is greater than 100%, region x time fixed effects, and household fixed effects. A dummy which equals 1 if my synthetic loan to value ratio (SLTV) measure is greater than 100% is used as an instrument for the likelihood that a household has negative home equity. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. In this case though cases with 100% decline in deposits are completely excluded from the analysis. Column 2 is the same as column 1 but excludes any changes larger than 25%. Column 3 is the same as column 1, but the dependent variable is the average of all monthly deposits over the whole time period for each household rather than the income at origination. Column 4 is the same as column 3 but excludes any declines larger than 25%. Column 5 is the same as column 1, but does not exclude any deposits and the dependent variable is a dummy equal to 1 if the household receives any social security checks. These are defined as direct deposits received on the 3rd of the month, or the 2nd, 3rd, or 4th Wednesday that are not explained by regularly scheduled labor related direct deposits. All standard errors are clustered at the MSA x cohort level.

	(1)	(2)	(3)	(4)	(5)

Observations (mil)	4.794	3.888	4.961	3.076	5.375

Table V. Elasticity for 2nd (Lower) Household Incomes

This table shows how the effect of negative equity on household income depends on the measure of income used. In particular, I look at how results change when consider only the Nth largest deposit each month. Just as in the main specifications Column 1 regresses the % change in deposits on an instrumented dummy equal to one if current mortgage loan to home value is greater than 100%, region x time fixed effects, and household fixed effects. A dummy which equals 1 if my synthetic loan to value ratio (SLTV) measure is greater than 100% is used as an instrument for the likelihood that a household has negative home equity. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. The dependent variable is the log of the largest deposit each month, where log(0) values are replaced with 0s. Column 2-4 are the same as column 1, but look at the 2nd-4th largest deposit each month respectively. All standard errors clustered at the MSA x Cohort level.

	(1)	(2)	(3)	(4)
	log(Dep+1)	log(Dep+1)	log(Dep+1)	log(Dep+1)
LTV>100 (IV: SLTV>100)	-0.43 (0.62)	-1.13* (0.63)	-1.61*** (0.65)	-1.84*** (0.67)

Observations (mil)	5.375	5.375	5.375	5.375

Table VI. Mortgage Mods, Negative Equity, and Labor Supply

This table shows how the relationship between income and current household mortgage loan to property value (LTV), after controlling for household specific factors and local demand shocks, varies in regions where mortgage modifications are more likely. Column 1 regresses the % change in deposits, where the numerator is the monthly deposit inflows and the denominator is the households income at the time of mortgage origination, on an instrumented dummy equal to one if the synthetic loan to value ratio (SLTV) measure is greater than 100%, region x time fixed effects, and household fixed effects. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. This is also interacted with the level of excess modifications per mortgage in a given MSA. This modification rate is the number of mortgages ever modified from 2010-2014 divided by the number of all outstanding mortgages over the same time period. The excess modification rate is the rate in a given MSA minus the average rate for all MSAs in the sample, divided by the standard deviation of these excess rates. Column 2 is the same as column 1, but also interacts the excess delinquency rate with negative SLTV. The delinquency rate is the number of mortgages ever 60 or more days past due from 2010-2014 divided by the number of all outstanding mortgages over the same time period. The excess delinquency rate is the rate in a given MSA minus the average rate for all MSAs in the sample, divided by the standard deviation of the excess rates. Column 3 is the same as column 1, but instead of the modification rate for all mortgages I use the modification rate among delinquent mortgages. The modification rate in this case is the number of mortgages ever modified from 2010-2014 divided by the number of mortgages ever 60 or more days past due over the same time period. Column 4 is the same as column 1 but instead of interacting negative SLTV with excess modifications, it interacts with a dummy variable equal to 1 if the state has judicial foreclosure requirements. The sample in this case is restricted to only households with 50 miles of a state border where the bordering states have different judicial foreclosure laws. Column 5 is the same as 4, but includes an interaction with if a state allows recourse for foreclosed properties. Column 6 is the same as 4, but requires the property to be within 50 miles of states with differing recourse laws and interacts negative SLTV with recourse instead of judicial foreclosure laws. The definition of state foreclosure laws comes from RealtyTrac.

Figure I. LTV vs. Income: Identification Based on Timing of Moving

This figure shows the relationship between income and current household mortgage loan to property value (LTV) after controlling for household specific factors and local demand shocks. This figure shows the coefficients of regression where I regress the % change in deposits, where the numerator is the monthly deposit inflows and the denominator is the households income at the time of mortgage origination, on dummies for various ranges of current (LTV) ratios, where house price is computed using original property value and changes in LPS MSA-level house price indices used by *MyBank* internally, region x time fixed effects, and household fixed effects. In this figure the x-axis indicator dummies for each household-month that appears in a given 10% LTV bucket and the right hand side are the co-efficients from the regression (shown in red). I normalize the fixed effect so buckets less than 100% sum to zero, allowing us to cleanly observe any changes that occur for high loan-to-value buckets. 95% confidence intervals computing standard errors clustered at the MSA x cohort level, are plotted with dotted lines on either side.

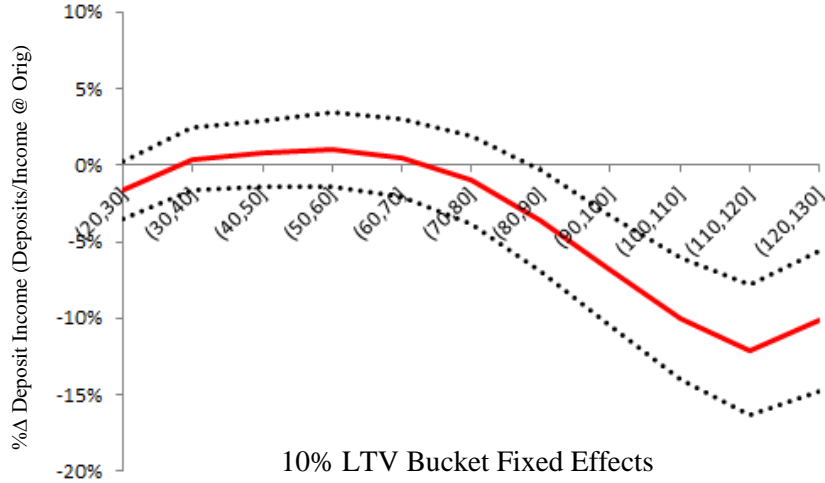

Figure II. LTV vs. Income: Identification Based HPI IV Reduced Form

This figure shows the average change in household income associated with negative household home equity using variation in the timing of home purchase as an instrument for the probability of having negative equity. This figure shows the coefficients of regression where I regress the % change in deposits, where the numerator is the monthly deposit inflows and the denominator is the households income at the time of mortgage origination, on dummies for various ranges of MSA-level house price index changes since mortgage origination, where house price is computed using original property value and changes in LPS MSA-level house price indices used by *MyBank* internally, region x time fixed effects, and household fixed effects. In this figure the x-axis are indicator dummies for each household-month that appears in a given 10% HPI change bucket and the right hand side are the co-efficients from the regression (shown in red). I normalize the fixed effect so buckets greater than 0% sum to zero, allowing us to cleanly observe any changes that occur for negative house price differences. 95% confidence intervals computing standard errors clustered at the MSA x cohort level, are plotted with dotted lines on either side.

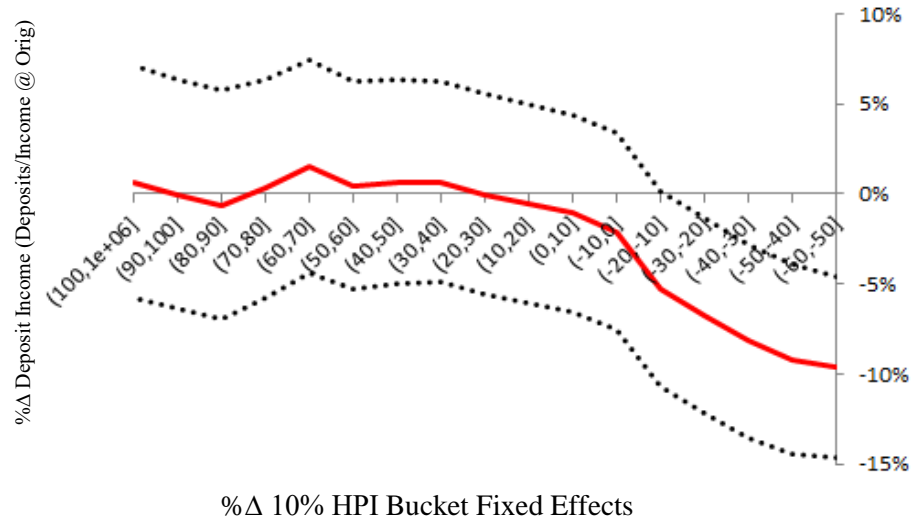

Figure III. Modification and Delinquency Rates vs. LTV

This figure shows how delinquency and modification rates vary with a household's mortgage loan to home value (LTV) ratio by 10% LTV buckets over the time period 2010-2014. Each unit of observation is at the household month level. The black line represents the % of households with a LTV ratio in a given month with the 10% range that will receive a mortgage modification in within the next year. The red dashed line is the percent who are ever at least 60 days past due on any mortgage interest payments.

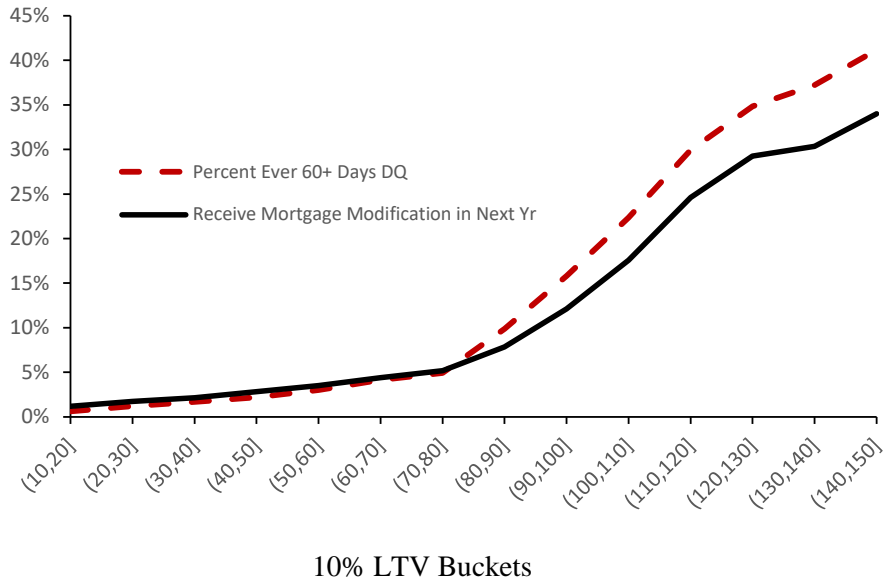

Figure IV. Mortgage Modifications and Labor Supply Event Study

In this figure I look at how household income changes for households who receive mortgage modifications around the dates they receive modifications. This figure plots the results from a regression of the % change in deposits, where the numerator is the monthly deposit inflows and the denominator is the household's income at the time of mortgage origination, on dummies for event time relative to the month a mortgage is modified, with time, loan age, and household fixed effects. The red line is the estimated coefficients from the event time dummies, normalized to zero for the pre-event period, and the dotted lines represent 95% confidence intervals for these estimates, using standard errors clustered at the household level.

Figure V. Mortgage Modifications and State Foreclosure Laws RD

This figure shows how mortgage modification rates discontinuously change at state borders with different foreclosure requirements. To be included in the sample it must be a MyBank mortgage, be at least 60+ days delinquent and at within at least 100 miles of a state border with differing foreclosure laws. Plotted in figure A are the coefficients of regressing mortgage modifications in a given month for mortgages 60+ days delinquent on fixed effects of each 10-mile bucket of distance from a state border for states with different laws concerning judicial foreclosure requirements (negative indicates a state with judicial foreclosure requirements), after controlling for 50 square mile fixed effects of the MSA of a mortgage. Figure B is the same as A, but focuses on recourse vs. non-recourse states, where negative values now refer to states with the possibility for recourse following mortgage foreclosures. Blue lines indicate all estimated coefficients, while the dashed black lines indicate 95% confidence intervals. The definition of state judicial foreclosure laws comes from RealtyTrac. The definition of state foreclosure laws comes from RealtyTrac.

Appendices

Appendix A: Panel Data Construction

The data provider for this project is a major U.S. financial institution, who I refer to as *MyBank*, with transaction-level client account information on more than 1/4th of all U.S. households over the 5 years from 2010-2014. For the purposes of this project I focus on households with sufficient *MyBank* relationships to estimate income and mortgage information and analyze income decisions at a monthly household level. Income is estimated using retail account deposit information and mortgage information is either derived from credit bureau data (only available for households w/ *MyBank* credit card accounts) or *MyBank* mortgage account information. In table A1 I detail the effect on sample size and household characteristics when multiple *MyBank* accounts are combined at a monthly frequency.

Table AI. Effect of Panel Data Construction on Sample Size

Merging is done at HH-level. To be included in the panel all households must have at least 12 months with deposits across all accounts $\geq \$100$ & $\leq \$25k$, a mean and median level of deposits across all accounts $\geq \$500$ & $\leq \$25k$. To be “active” a HH must have at least \$200 aggregated across all accounts in a month or at least \$100 in deposits across all accounts. For direct deposits and assigned to jobs direct deposits the same restrictions apply as with deposits, but for direct deposits and assigned direct deposits only respectively, and $\geq 75\%$ of all deposits must be via the channel of interest. 1st row includes no filters, but all others that include retail include the filter.

	Median Ann. Deposits	Median MTG Bal	# HH- Mo Obs (mil)	# Acct (mil)	# Cust (mil)	# HHs (mil)

Table BII. *MyBank* Summary Stats vs. Survey of Consumer Finance

To be included in the panel all households must have at least 12 months with deposits across all accounts $\geq \$100$ & $\leq \$50k$ and a mean and median level of deposits across all accounts $\geq \$500$ & $\leq \$25k$. For direct deposits the HH must have at least 12 months of direct deposits $\geq \$100$ & $\leq \$25k$, a mean and median level of direct deposits across all accounts $\geq \$500$ & $\leq \$25k$ and $\geq 75\%$ of all deposits must be via the direct deposit channel. All data winsorised at 99th percentile. This sample includes only households that have retail and mortgage accounts at *MyBank* from 2010-2014. Data from Survey of Consumer Finance (SCF) comes from 2010 and includes all households with a primary mortgage outstanding balance of at least \$1,000 (13,580 households).

	SCF Median (2010)	<i>MyBank</i> Median	<i>MyBank</i> Std. Dev

Is Fixed Rate	87.4%	83.9%	

Table BIII. Income vs. LTV

This table shows the relationship between income and current household mortgage loan to property value (LTV) after controlling for household specific factors and local demand shocks. Column 1 regresses the % change in deposits, where the numerator is the monthly deposit inflows and the denominator is the households income at the time of mortgage origination, on dummies for various ranges of current (LTV) ratios (where house price is computed using original property value and changes in LPS MSA-level house price indices used by *MyBank* internally), region x time fixed effects, origination buckets interacted with time fixed effects, controls for household level mortgage pre-payments, mortgage age, and income at origination. Column 2 is the same as column 1, but instead of a variety of household specific controls includes household fixed effects. Column 3 is the same as 2, but the numerator in the dependent variable proxy for income is direct deposit inflows rather than all deposit inflows. All standard errors clustered at the MSA x Cohort level.

	(1)	(2)	(3)
	% Δ Deposits	% Δ Deposits	% Δ Direct Deposits
50 < LTV < 90	-0.83 (0.91)	-2.60*** (0.45)	-3.97** (0.32)
90 < LTV < 100	-4.15*** (1.40)	-4.48*** (0.64)	-4.55*** (0.42)
100 < LTV < 110	-4.98*** (1.69)	-5.46*** (0.75)	-5.01*** (0.48)
110 < LTV	-4.46*** (2.08)	-4.15*** (0.88)	-5.51*** (0.60)

Table BIV. Robust to Normalization

This table shows that the negative effect of mortgage loan-to-value (LTV) on labor supply is robust to the choice of normalization and method of clustering standard errors. Just as in the main specifications Column 1 regresses the % change in deposits on an instrumented dummy equal to one if current mortgage loan to home value is greater than 100%, region x time fixed effects, and household fixed effects. A dummy which equals 1 if my synthetic loan to value ratio (SLTV) measure is greater than 100% is used as an instrument for the likelihood that a household has negative home equity. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. The numerator is still the monthly deposit inflows, but in this case the denominator is the households average monthly deposit inflows over the entire sample period. Column 2 is the same as column 1, but includes direct deposits instead of all deposits. Column 3 is the same as column 1 but the dependent variable is the log of all monthly deposit inflows, with nothing in the denominator. For households with 0 deposits in a given month, but with a still active account \$1 was included instead. Column 4 is the same as column 3 of table 3, but standard errors are clustered at the MSA instead of MSA x cohort level.

	(1)	(2)	(3)	(4)	(5)
	% Δ Dep	% Δ DirDep	log(1+Dep)	% Δ Dep	% Δ Dep
LTV>100 (IV: SLTV>100)	-4.87*** (0.73)	-2.23** (1.10)	-4.50** (1.85)	-3.69*** (0.84)	-5.58*** (2.15)

Observations (mil)	5.375	4.788	5.375	5.375	2.914

Table BV. Income vs. LTV: All Liabilities

This table shows that the effect of negative equity on household income is robust to including all liabilities as reported by the credit bureau. Similar to the main specifications Column 1 regresses the % change in deposits on an instrumented dummy equal to one if all outstanding liabilities divided by the home value is greater than 100%, region x time fixed effects, and household fixed effects. A dummy which equals 1 if my synthetic loan to value ratio (SLTV) measure is greater than 100% is used as an instrument for the likelihood that a household has negative home equity. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. The dependent variable is all deposits each month normalized by the reported income at origination. The sample analyzed is restricted to only households that have *MyBank* mortgage, credit card, and retail accounts. Column 2 is the 1st stage of the instrumental variable regression run in column 1. All standard errors clustered at the MSA x Cohort level.

	(1)	(2)
	% Δ Dep	LTV>100

Adjusted R ²	0.623	0.798
Observations (mil)	3.555	3.555

Table BVI. Income vs. LTV: Current vs. Delinquent Borrowers

This table shows that the effect of negative equity on household income is driven by households that are not delinquent on their mortgage payments. Just as in the main specifications Column 1 regresses the % change in deposits on an instrumented dummy equal to one if current mortgage loan to home value is greater than 100%, region x time fixed effects, and household fixed effects. A dummy which equals 1 if my synthetic loan to value ratio (SLTV) measure is greater than 100% is used as an instrument for the likelihood that a household has negative home equity. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. The dependent variable is all deposits each month normalized by the reported income at origination. The sample analyzed is restricted to only mortgages that are current on all payments. Column 2 is the same as column 1, but run on the sample of households who are delinquent or foreclosed on their mortgage. All standard errors clustered at the MSA x Cohort level.

	(1)	(2)
	% Δ Dep	% Δ Dep
LTV>100	-3.97***	2.44
(IV: SLTV>100)	(0.57)	(1.53)

Adjusted R ²	0.624	0.623
Observations (mil)	4.957	0.247

Table BVII. Mortgages at Non-*MyBank* Lenders

This table shows the relationship between income and current household mortgage loan to property value (LTV) after controlling for household specific factors and local demand shocks is not driven by households who deposit and lend at the same institution hiding income. I do this by using credit bureau data to look at households with *MyBank* retail and credit card accounts but who get mortgages from another lender. Column 1 monthly deposit inflows on an dummy equal to one if my synthetic loan to value ratio (SLTV) measure is greater than 100%, region x time fixed effects, household fixed effects, and home purchase cohort date x time fixed effects. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. Column 2 is the same as column 1 but restricts the analysis to only households with mortgages not serviced or owned by *MyBank*.

	(1)	(2)
	\$ΔMonthly Deposits	\$ΔMonthly Deposits
SLTV>100	-48.8*** (10.4)	-65.0*** (15.0)

Adjusted R ²	0.344	0.348
Observations (mil)	20.113	15.018

Table BVIII. Elasticity by Nth Largest Deposit Each Month

This table shows how the effect of negative equity on household income depends on the measure of income used. In particular I look at how results change when consider only the Nth largest deposit each month. Just as in the main specifications Column 1 regresses the % change in deposits on an instrumented dummy equal to one if current mortgage loan to home value is greater than 100%, region x time fixed effects, and household fixed effects. A dummy which equals 1 if my synthetic loan to value ratio (SLTV) measure is greater than 100% is used as an instrument for the likelihood that a household has negative home equity. SLTV is an instrument for loan-to-value that does not depend on household specific factors, except the timing of moving, and varies at the region-time-cohort level. The numerator is the largest deposit each month and the denominator is the mean of the largest monthly deposits during the sample period. Column 2-4 are the same as column 1, but look at the 2nd-4th largest deposit each month respectively. All standard errors clustered at the MSA x Cohort level.

	(1)	(2)	(3)	(4)
	% Δ Dep	% Δ Dep	% Δ Dep	% Δ Dep
LTV>100 (IV: SLTV>100)	-0.41 (0.57)	-1.11** (0.53)	-1.52*** (0.54)	-1.72*** (0.55)

Table BIX. Mortgage Mods and State Foreclosure Laws RD

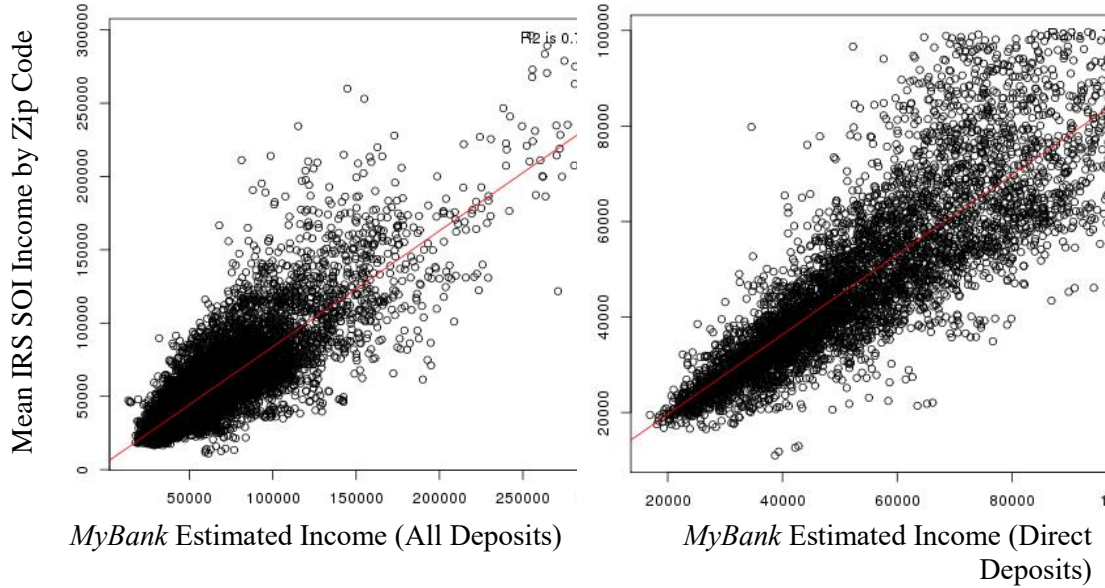

This table examines how mortgage modification rates vary discontinuously along state borders with differing foreclosure laws. The sample includes a cross-section, not time series component, of any MyBank mortgage account, not household, within 50 miles of a state border with differing foreclosure laws from 2010-2014. In column 1 I regress a dummy variable equal to one if the mortgage ever receives a modification on a dummy variable equal to one of the state has judicial foreclosure requirements, after controlling for 100 square mile fixed effects around the border, distance to border (signed to be negative if state has judicial foreclosure requirements), distance to border squared, and distance to border cubed. Column 2 is the same as 1, but includes only those mortgages that are ever at least 60+ days delinquent. Column 3 is the same as 2, but includes only those mortgages that are ever at least 90+ days delinquent. Column 4 is the same as 2, but only includes those MSAs on state borders with differing recourse laws in foreclosure and a dummy variable for a state having recourse laws, instead of the judicial foreclosure dummy. Standard errors are clustered at the MSA level.

	(1)	(2)	(3)	(4)
	Mod (%)	Mod (%)	Mod (%)	Mod (%)

Figure BI. Validity of Income Measure

A. Zip-Code Level Mean Income IRS SOI vs. MyBank (2010-2013)

These figures compare the mean incomes by zip code from 2010-2013. To be included there must be at least 4,000 IRS SOI returns and at least 1,000 *MyBank* observations per zip-code year w/ filters applied. To be included in the panel all households must have at least 12 months with deposits across all accounts $\geq \$100$ & $\leq \$25k$, a mean and median level of deposits across all accounts $\geq \$500$ & $\leq \$25k$. For direct deposits the HH must have at least 12 months of direct deposits $\geq \$100$ & $\leq \$25k$, a mean and median level of direct deposits across all accounts $\geq \$500$ & $\leq \$25k$ and $\geq 75\%$ of all deposits must be via the direct deposit channel.

Correlations	All Deposits	All Direct Deposits	All Jobs
<i>MyBank</i> Retail Acct	0.832	0.886	0.911
<i>MyBank</i> RTL, CC, & Any MTG	0.838	0.777	0.736

B. Estimated Income vs. MyBank @ Origination Distribution

This figure compares the cumulative distribution of reported income at mortgage origination for *MyBank* mortgages with the estimated income based on retail deposits for all households in the same calendar year for all households with data available for both, who meet the filter requirements. To be included in the panel all households must have at least 12 months with deposits across all accounts and years $\geq \$100$ & $\leq \$25k$, a mean and median level of deposits across all accounts and years $\geq \$500$ & $\leq \$25k$. For direct deposits the HH must have at least 12 months of direct deposits $\geq \$100$ & $\leq \$25k$, a mean and median level of direct deposits across all accounts $\geq \$500$ & $\leq \$25k$ and $\geq 75\%$ of all deposits must be via the direct deposit channel. The table below includes the pair-wise individual correlations for each household for all three measures of income.

Correlation	All Deposits	Direct Deposits	Job Direct Deposits
<i>MyBank</i> RTL & CC & Any MTG	0.378	0.511	0.449

Figure BII. Validity of Delinquency Measure

This figure compares a time series of mortgage delinquency rates for households with mortgage at *MyBank* using *MyBank's* internal mortgage data with national seasonally adjusted quarterly mortgage delinquency rates published by Federal Reserve Economic Data (FRED) from 2009-2014. Quarterly data from are interpolated between quarters to provided monthly estimates. The green and blue top lines for both FRED and *MyBank* represent the percent of all mortgages that are at least 30 days past due. The red bottom line represents all *MyBank* mortgages that are at least 90 days past due.
