Abstract

Using a novel dataset of over 3,500 public and private firms, we construct the network of firm connections through executives and directors on the eve of the 1929 financial market crash. We find that more connected firms have 17% higher 10-year survival rates on average. Consistent with a role in facilitating access to working capital, the results are particularly strong for small firms, private firms, cash-poor firms, and firms located in counties with high bank suspension rates during the crisis. Moreover, connections to cash-rich firms that increase their accounts receivable during the peak of the crisis are most important for survival. Our results suggest that network connections can play a stabilizing role during a financial crisis by easing the flow of capital to constrained firms.

Abhilasha Anantharamakrishnan, Shivam Choudhary, Antony Anyosa Galvez, Fotis Grigoris, Jason Kang, Alexander Keith, Thao Mai, Aksh Nijhara, Tianshu Ren, Amey Sharma, Yidi Wu, and Zhen Ye provided excellent research assistance. All remaining errors are our own.

1. Introduction

Firm failures during a crisis can lead to job losses and additional deterioration in demand. Thus, it is important to understand the factors that mitigate or exacerbate financial fragility in response to negative economic shocks. A factor that has received prominent attention in the recent literature is the role of business connections. For example, network connections between banks through shared deposits appear to promote fragility by providing a mechanism for shocks to spread among connected institutions (Calomiris, Jaremski, and Wheelock, 2019; Mitchener and Richardson, 2019; Das, Mitchener, and Vossmeier, 2018). Ownership links among industrial firms have a similar effect: the plants of multi-unit firms are more responsive to shocks that occur in other localities in which the firm operates than are local single-plant peers (Giroud and Mueller, 2017; Loualiche, Vickers, and Ziebarth, 2019). Likewise, supply chain links between industrial firms can propagate idiosyncratic shocks from one firm or industry to down- or upstream firms (Ahern, 2013). On the other hand, firms can use trade credit and other forms of financial assistance from industrial peers to substitute for external finance during a crisis (Buchuk et al, forthcoming; Santioni, Schiantarelli, and Strahan, 2017; Almeida, Kim, and Kim 2015; Gao, 2014; Garcia-Appendini and Montoriol-Garriga, 2013).

We use novel data from the Great Depression to study the effect of executive and director network connections on firm fragility in response to a financial crisis. Information flow through the personal connections of top decision-makers could exacerbate the crisis by facilitating herding (Banerjee, 1992; Bikhchandani, Hirshleifer, and Welch, 1992). But, it could also be essential to allow executives to evaluate the costs and benefits of undertaking an intermediation role normally performed by the financial sector, consistent with Ellison and Fudenberg (1993, 1995). Focusing on firm failure as a measure of fragility, we document that director and executive connections are

associated with economically larger 10-year survival probabilities: a firm with more connections than the median firm has a probability of failure that is roughly 3.4 percentage points lower during the Depression years than a firm with fewer connections than the median firm – a 17% decrease from the mean failure rate of 20%. Moreover, the effects are the most pronounced among firms in counties that experienced the highest rates of bank failure between 1928 and 1933.

We focus on the Great Depression for several reasons. First, the Depression is the largest negative economic shock to U.S. markets during the time period for which we can collect comprehensive data on industrial firms from Moody's Manuals.¹ Unlike other downturns, the Depression was accompanied by high rates of firm failure, implying that many firms were unable to weather the shock by spending out of their own cash reserves or by reducing expenditures. Moreover, the severity of financial disruptions during the Depression varied significantly at the local level because of segmentation in the banking industry (Calomiris and Mason, 2003a, 2003b; Nanda and Nicholas, 2014), providing a source of variation in the cross-section that we can use to identify responses to the shock. Similarly, we can exploit the local nature of the director markets of the era to provide a plausibly exogenous source of variation in director network connections.

In addition, we observe large subsamples of publicly traded and privately held firms for which the outcome of interest – firm failure – is directly comparable. Private firms, which comprise roughly 60% of our sample, appear to be more similar in size to publicly traded firms than we typically observe in recent data.² Thus, it is more credible to make cross-group comparisons to determine the effect of additional sources of finance. Moreover, public listing does not entail the

¹ Peak U.S. unemployment was roughly 25% during the Great Depression with unemployment exceeding 10% throughout the 1930s. By contrast peak unemployment during the 2009 Financial Crisis was under 10%.

² See, e.g., Asker, Farre-Mensa, and Ljungqvist (2015) for a recent sample that allows comparisons across publicly traded and privately held firms. In our sample, the median publicly traded firm in 1928 has assets that would place it at the 85th percentile among private firms. Conversely, the median private firm has assets that would place it at the 20th percentile among publicly traded firms. Thus, as in recent data, private firms are smaller than public firms; however, the overlap of the size distributions appears to be more substantial.

same bundle of additional regulatory requirements as it does today. For example, the independence requirements in regulations such as the Sarbanes Oxley Act of 2002 could constrain the ability of firms to construct optimal networks. If this is the case, historical data can allow us to study the stabilizing effects of network conditions in a setting in which firms are not bound by these constraints.³ By contrast, we cannot observe the appropriate counterfactual in modern data without making cross-country comparisons. Thus, our analysis provides unique evidence on the attractiveness of alternative policy regimes in the context of a major financial shock. Of course, intertemporal differences in regulatory regimes could have many other effects, including a potential increase in agency costs in good times. Our goal is not to analyze the broader tradeoffs between the costs and benefits of governance regulations.

A challenge for all analyses of network effects is that network ties are not randomly assigned. Our analysis of differential outcomes following the 1929 financial shock addresses some sources of concern. In particular, it is unlikely that firms create the connections we observe in 1928 in anticipation of the coming Depression. Thus, to the extent that highly connected and less connected firms are otherwise similar, conditional on a battery of controls that includes state and industry fixed effects, we can interpret the ex ante differences in connections as exogenous for the purposes of identifying the effect of connections on responses to the shock. The remaining concern is that there is an omitted, unobservable factor that positively correlates with network connections and also predicts heightened survival odds during the Depression.

³ It is not the case that firms were entirely unconstrained in their director choices during our sample period. The Clayton Act of 1914 prohibited firms from choosing directors who were already serving on the boards of competing companies. The standard for “competing companies,” was two companies that would violate antitrust criteria by merging. The data suggest that the interpretation of this standard for enforcement purposes was not very aggressive; shared directorships between companies in the same broad industry groups were quite common.

As described above, we use the greater segmentation of markets during the Depression era as a source of plausibly exogenous local variation that we can exploit for identification. First, we build on the approach from Nanda and Nicolas (2014) by exploiting county-level variation in bank distress rates. Because of restrictions on interstate branching, local banks were an important source of working capital financing in the 1920s and 1930s, even for large firms. Thus, we can use variation in the distress rate of local banks to measure variation in the intensity of the financial shock faced by firms. We find a much stronger positive effect of network connections on firm survival among firms that are located in areas with more local bank distress between 1930 and 1933. This result addresses the omitted variable concern under the plausible assumption that counties with more bank distress are not also counties that are home to firms of (unobservable) ex ante higher quality. Second, we exploit the local nature of director markets in the 1920s and 1930s. We construct an instrument for network ties that isolates variation in the demand for directors' services in other local firms due to variation in the average sizes of the boards of in-state firms in their industry, conditional on the total number of in-state, in-industry firms (and other measures of local market activity). We find a positive relation between the instrumented number of network connections to other firms and a firm's likelihood of survival. The results provide a causal interpretation under the assumption that small average board sizes in a state-industry pair, conditional on a wide set of controls including the firm's own board size, affect firm survival only through their positive correlation with network connections.

As a third way to address the endogeneity concern, we measure heterogeneity in the effect of connections in the cross-section of firms. Under a causal interpretation, connections should provide the most assistance during the crisis to firms that would otherwise be more prone to fail, such as financially constrained firms or firms with poor access to information about changing

fundamentals. We indeed find that the effect of connections is concentrated among small, private, cash-poor, and rural firms, characteristics that generally predict heightened failure rates during the Depression. For these firms, the magnitude of the effect of connections on survival probabilities is two to three times our baseline estimate. Thus, to explain our results, an omitted factor would not only need to positively correlate with connections and survival probabilities, but also have its primary influence among the most constrained firms.

As a final step, we provide evidence to distinguish among several economic channels through which network connections could aid firms during the crisis. First, we test whether firms use their network links to access credit from connected firms. Consistent with this channel, we find that the effect of network connections on survival derives primarily from connections of financially constrained to cash-rich firms. Moreover, we find that it is connections to cash-rich firms that increase their accounts receivable during the credit crunch from 1929 to 1933 that matter the most, suggesting that firms use trade credit as a mechanism to extend finance to connected trading partners. Second, we test whether connections increase the odds that firms survive the crisis by facilitating price coordination in product markets (i.e., softening competition). Consistent with this channel, we find that connections to within-industry peers matter more for survival than out-of-industry links. However, we also find that those within-industry links matter more when they are to out-of-state firms than to in-state firms. Because such firms are less likely to compete in the same product markets, this evidence is perhaps more consistent with the extension of trade credit along a vertical supply chain than with product market collusion. Third, we test whether connections between firms are due to the presence of commercial bankers who sit on multiple boards and ease access to credit during the crisis by mitigating information asymmetries. We find that the effect of connections remains when we purge all potential bankers from our sample of

connected directors. More generally, we find that our results exist even among firms that did not have outstanding bank debt at the outset of the crisis. Thus, while connections to banks likely do assist troubled firms (Frydman and Hilt, 2017), our analysis uncovers a distinct mechanism. We also do not find any evidence that network connections proxy for the benefits of connections to major financial centers, i.e., cities with active local stock markets. Finally, we test whether firms with more connections attract more equity investments from other industrial firms. We find that connected firms are indeed more likely to become acquisition targets during the crisis; however, the effect is not concentrated in the same types of firm (small, cash poor) in which we observe heightened survival probabilities.

Overall, our results suggest that networks have their largest effect by facilitating access to capital from other, less constrained industrial firms, though the mechanisms we consider are not mutually exclusive. This access to capital from connected firms is associated in turn with lower firm failure rates. The economic mechanism that we identify is likely to generalize to other crisis episodes that are characterized by significant risk of firm failure, such as the economic shock precipitated by Covid-19. Moreover, our results point to a possible externality from policies to support the financial health of large, connected firms during a crisis: those firms are likely to have an information advantage in transferring needed capital to constrained trading partners.

Our analysis makes several contributions to the literature. First, we provide novel evidence on the role of economic networks during financial crises. The banking literature largely identifies network connections as an amplification mechanism for shocks to the credit market (Calomiris, Jaremski, and Wheelock, 2019; Mitchener and Richardson, 2019; Das, Mitchener, and Vossmeier, 2018). Evidence on the effects of ownership and product market links among industrial firms is mixed: some studies find evidence of a similar amplification mechanism (Loulache, Vickers, and

Ziebarth, 2019; Giroud and Mueller, 2017, Ahern, 2013) while others find evidence that firms use such links to access financing when credit markets freeze (Buchuk et al, forthcoming; Santioni, Schiantarelli, and Strahan, 2017; Almeida, Kim, and Kim 2015; Gao, 2014; Garcia-Appendini and Montoriol-Garriga, 2013). We study a different kind of link: network connections through shared directors and executives. We find that these connections are a stabilizing force during a financial crisis. Our results suggest that director and executive connections lower the information costs associated with providing funding to distressed firms, allowing industrial firms to substitute for banks as providers of working capital. Moreover, the benefits of providing such assistance are likely to be largest when the recipient firm is a customer or supplier that might otherwise fail. Thus, our evidence provides novel insight into the conditions under which trade credit and product market connections are likely to provide a stabilization rather than an amplification mechanism. Literature of the era noted the steep decline in bank lending as a source of corporate financing: business loans comprised around 40 percent of bank earning assets in 1929, falling to less than 20% by 1936 (Reifer, Friday, Lichtenstein, and Riddle, 1937). This fact raised speculation as to the degree that industrial firms might have partially displaced banks in providing working capital to the system. Our results support this conjecture and also point to the economic conditions under which industrial firms are willing to play this role.

Our analysis also contributes to the existing literature on executive and director networks. Many existing papers focus on either the implications of network ties for corporate governance (Fracassi and Tate, 2012; Hwang and Kim, 2009; Nguyen, 2012; Schmidt, 2015) or the correlation of corporate policies such as investment and compensation across firms (Fracassi, 2017; Shue, 2013). Work that links networks with access to financial capital typically focuses on connections to financial institutions (Guner, Malmendier, and Tate, 2008; Engelberg, Gao, and Parsons, 2012;

Frydman and Hilt, 2017). A partial exception is Huang, Jiang, and Lie (2012), who find evidence that connected firms among the S&P 1500 have stronger operating performance around the 2008 financial crisis. However, they also emphasize the role of personal connections with lenders in their analysis, finding that firms in financial distress between 1998 and 2009 have a lower probability of filing for bankruptcy when they have such linkages. Our sole focus, instead, is on network links among industrial firms, not links to financial institutions, and on analyzing the economic channels through which they promote stability in times of crisis.

Finally, we provide new insight into how disruptions to the financial system affected business outcomes during the Great Depression. Existing work debates the relative importance of a number of financial factors for outcomes during the Depression.⁴ Most relevant to our analysis is the literature focusing on the effects of bank failures. Existing work finds that bank failures had large negative effects on state-level income growth (Calomiris and Mason, 2003b). Recent work also links bank failures to business outcomes including revenue growth (Ziebarth, 2013), innovation (Nanda and Nicholas, 2014), and employment growth (Ziebarth, 2013; Lee and Mezzanotti, 2017; Benmelech, Frydman, and Papanikolaou, 2019). In our analysis, we likewise observe a significant effect of local bank failure on the probability of firm failure. We build on this literature by analyzing the interaction of banking shocks with firm-level network effects, using a novel hand-collected dataset of the executive and director connections among 3,753 firms in 1928.⁵ Given the documented effects of connections among banks themselves, we might expect firm networks to propagate shocks from firms that are directly affected by the failure of a lending

⁴ See Calomiris (1993) for a discussion of the relative importance of several different events in financial markets for outcomes during the Depression.

⁵ The existing networking literature focuses almost exclusively on BoardEx data from the post-2000 period. An exception is a limited literature in sociology that examines the long-term evolution of board interlocks among the largest U.S. corporations (e.g., Mizruchi, 1982; Mizruchi, 1983). However, that literature generally focuses on characteristics of the network itself rather than its consequences for corporate outcomes using smaller cross-sections of firms. For example, Mizruchi (1983) analyzes a sample of 167 large firms.

bank to connected firms that are not. However, we instead find that they are a mitigating force: information flow between connected executives and directors facilitates the flow of finance from cash-rich to distressed industrial firms.

2. Data

To conduct our analysis of the effect of network ties on firm survival probabilities, we use the 1928 volume of the Moody's Industrial Manual to construct a novel mapping of the links between directors and executives of industrial firms. We collect information on the executives and directors of all firms in the manual, including both public and private firms, but excluding foreign firms and subsidiaries. Here we outline the basics of the data collection and variable construction. For a more detailed description, see the Data Appendix. We obtain a final dataset of 3,753 firms between which we measure network links based on the presence of either a common director or an executive in one company who serves as a director in the other. To our knowledge, our sample provides the broadest coverage of firms from the era in the existing literature.

We also collect a variety of financial information for each company from the 1928 manual. The manual contains fairly detailed accountings of firms' financial liabilities as of the end of the fiscal year prior to the manual's publication. We record the total value of each firm's outstanding debt and the identity of the stock exchanges on which it is listed. We also record the value of firms' cash holdings and total assets. Compared to balance sheet information, the information on income statement items in the manuals, such as sales or net income, tends to be less standardized across firms and is also less often available. Where available, we record the bottom line of firms' income statements and refer to it as "net income."⁶ We also obtain unusually rich information on the

⁶ We also record the top line of firms' income statements and refer to it as "sales." In general, we use these variables sparingly in our analysis. The measures are noisy. For example, though some firms directly report sales, many others report only gross profit or another accounting item that is already adjusted from top-line sales. They are also often

geography of firms from the manuals: for each firm we record the locations of all the firms' offices. Finally, though we do not observe standardized industry codes such as SIC or NAICS codes, we use information on the nation's "basic industries" contained in the manual to construct an industry classification. Our approach to measuring industries is similar in spirit to that of Hoberg and Phillips (2016). We retrieve key words from the description of each industry in the manual and then search for the key words in the description of each firm. We use the relative frequencies of the key words from each industry to assign sample firms to industries, allowing the possibility that firms match to multiple industries.⁷ In the Data Appendix, we provide additional details on the construction of our industry measures. We also validate the classification by showing that our industry groups have significant explanatory power for the cross-section of leverage above and beyond standard controls. (Data Appendix Table 4 shows that the increment to adjusted R^2 from adding industry fixed effects ranges from five to eight percentage points, an effect similar in magnitude to what we observe in cross-sections of Compustat data from 1980 and 1990 using Fama-French 30 industry classifications.)

We use information from the 1938 manual to construct our main dependent variables: (1) an indicator variable that is equal to one if a firm fails by 1937 and (2) an indicator variable that is equal to one if a firm is acquired or merges with another firm by 1937.⁸ The manual contains a list of companies that were included in the 1928 to 1937 manuals, but that are not included in the 1938

missing: Net income information is available for roughly 70% of the sample, and sales data for only 60%, severely reducing our power. Moreover, the data is more often missing for small firms, which are of particular interest in our analysis. Though sales/assets provides a better measure of ROA than net income/assets, we typically use the latter when we require a performance measure because it is more often available. In all cases we directly control for leverage differences that could make the measure difficult to compare across firms.

⁷ Though we allow firms to have multiple industry classifications, we typically require the frequency of industry key words as a fraction of the total frequency of industry key words across all industries to be greater than 25% to limit noise in the classification scheme.

⁸ Cases in which the firm is the target of an acquisition vastly outnumber cases in which the firm merges with another firm: out of 326 firms that exit due to M&A activity, 17.8% of firms are merged into another firm and 82.2% are acquired.

manual, and the reason for their exclusion. We use this list to construct the dependent variables. We do not count name changes as failures. We also do not count firms that are acquired as failing since our economic hypothesis makes opposite predictions for the relation between the two outcomes and connections.

An advantage of using firm survival as our main outcome measure is that it is consistently measured and directly comparable across firms, both public and private. However, using firm survival as our outcome measure means that we must be cautious about making general welfare claims. Survival is in the private interests of the firm's claimholders, but could be socially inefficient. Nevertheless, in the context of network ties, such an outcome would require inefficient investment choices by outsiders to whom the firm's executives and directors share connections. An alternative approach could be to study differences in accounting variables such as asset or sales growth. However, our interest is in the effect of network connections around a major negative shock. If there are significant differences in firm survival rates across treated and untreated firms, then differences in growth rates are difficult to interpret. For example, if firms with slower growth rates are at greater risk of failure and network connections increase the odds of survival, then network connections might predict lower growth rates conditional on firm survival (particularly if the primary economic effect of connected firms is to function as "financiers of last resort"). It would be incorrect to interpret such a result as evidence that connections harm connected firms.

As our main measure of network connections, we compute each firm's degree centrality, or the total number of connections it has through its executives and directors to other firms in the sample (*Total Connections*). To help tease out the mechanism through which connections matter for firm survival, we also consider several partitions of the network. We consider separately the subsets of connections to cash-rich firms and connections to cash-poor firms. We define a firm as

cash-rich (cash-poor) if its cash holdings scaled by total assets are larger (smaller) than the sample median. Similarly, we consider separately connections to firms that increase and decrease accounts receivable during the peak Depression period of 1928 to 1933. We also consider two other partitions to distinguish between “local” and “distant” connections: connections within and outside the firm’s industry and connections within and outside the states in which the firm has offices. All connections measures are likely to have a mechanical positive correlation with board size. Thus, we include board size as a key control variable in all of our analysis.

Our degree centrality measures capture direct connections between pairs of companies, or the number of paths of length one that include each firm. Another way to characterize the director network is by calculating each firm’s eigenvector centrality. This measure instead counts the number of paths of all lengths that include the firm. In our sample, the two measures are strongly positively correlated (0.67). Nevertheless, they could capture different economic channels through which networks affect firm survival. Direct firm-to-firm assistance – e.g., through the provision of trade credit – could be better captured by the degree centrality measure while general access to economic information could be better captured by the eigenvector measure. Though the two measures generally relate to firm survival in a similar way, we find stronger relations between degree centrality and firm survival and thus focus our analysis on that measure.⁹

In Table 1, we report summary statistics of the data. The mean (median) firm in our sample has total assets of \$16.029M (\$4.259M) in 1927 dollars. These numbers translate into roughly \$240M (\$64.5M) in 2017 dollars. Among small firms with total assets less than the sample median,

⁹ Consistent with our economic interpretation of the measures, the eigenvector measure has the strongest relation with the probability that a firm is acquired. Taking this analysis a step further, we find that the relations between degree centrality and firm survival (or the likelihood of being acquired) hold even after controlling for the firm’s eigenvector centrality. This result suggests it is indeed direct firm-to-firm relationships that matter most in the context of a negative financial shock.

mean (median) total assets are \$2.158M (\$2.050M). Thus, our larger sample size compared to other studies of Depression era firms does not appear to come from filling the sample with large numbers of tiny firms. The mean (median) firm has cash holdings equal to 8.6% (4.9%) of total assets. The mean (median) firm has 8.2 (7) directors on the board, which roughly equals the mean of *Total Connections* (7.5). Connections to cash-rich firms are more common than connections to cash-poor firms, consistent with those connections having greater value to the firm. Though connections to firms that increased receivables between 1928 and 1933 could be similarly valuable, we find that they are far less common than connections to firms that decrease receivables, consistent with the unanticipated nature of the shock and firms' differential responses to it. 20% of firms in 1928 disappeared by 1937 and an additional 10.8% were acquired by another firm. We observe a reasonably rich distribution of firms across industries. Geographically, we observe firms operating in 49 distinct states (we do not observe any firms in Alaska, which was not a U.S. state at the time), though there are noticeable clusters of firms in New York and Massachusetts. We use state fixed effects in our analysis to correct for differences across state markets. However, the distribution of firms geographically also allows us to test for differential effects of connections across different types of local markets.

In Table 2, we report pairwise correlations of several of our key dependent and independent variables. Notably, we observe a strong and statistically significant negative correlation between the *TotalConnections* measure and the indicator variable for firm failure by 1937. We also observe that network ties are less frequent among private firms and among firms in rural areas. These correlations are consistent with geographic segmentation in the director labor market, a feature we exploit for identification later in the paper. We do not observe a significant correlation between

connections and 1928 financial leverage and observe only a weak correlation with cash holdings, suggesting that network measures do not proxy for better pre-crisis access to capital markets.

3. Network Connections and Firm Survival

The null hypothesis of our tests is that director and executive network ties to other firms do not affect the likelihood of firm failure during the Depression. Alternatively, the value of information that is available through network ties could be high at the time of a negative economic shock, when uncertainty is high. If so, then, network ties could increase survival odds, for example, by easing access to finance among (unexpectedly) financially constrained firms.

3.1. *Baseline Regressions*

Our initial approach to identifying the effect of network connections on firm survival is to employ a strategy similar in spirit to Opler and Titman (1994). We exploit a sudden and unexpected shock, the financial market crash of 1929, and compare the performance of firms with many network ties to other firms with the performance of firms that have few network ties to other firms prior to the shock. Our identifying assumption is that we can treat firms' pre-existing network ties as exogenous with respect to the shock. Thus, we essentially compare differences in responses across firms that happened to have more and fewer network ties at the time of the shock. Because the market crash in 1929 is an unanticipated event, the assumption that firms did not endogenously form network links in anticipation of the shock knowing that they would mitigate its negative impacts is clearly plausible (i.e., reverse causality is not a major concern).

As a starting point, we present visual evidence of the relation between network connections and failure. In Figure 1, we graph the network of industrial firms in 1928. Each vertex on the graph represents a firm; firms that failed by 1937 are colored red and firms that survived are green. We exclude firms with no connections from the figure. Towards the center of the graph, we observe a

dense cluster of green dots. Red dots (or failing firms) become more common as we move toward the perimeter of the figure. Moreover, failure rates among isolated firms (excluded from the picture) are more than ten percentage points higher than they are among firms with at least one connection. This basic pattern between network connections and firm survival is statistically significant if we estimate it within a simple univariate regression.

The main threat to identification is that network ties are correlated with an omitted factor that also predicts survival rates in response to the shock. Our first approach to address this concern is to saturate a regression model with fixed effects and controls. In the remainder of the Section, we provide additional analysis to bolster the causal interpretation.

To begin, we estimate the following linear probability model:

$$Y_{i1938} = \beta_0 + \beta_1 \text{Connections}_{i1928} + \mathbf{X}'_{i1928} \boldsymbol{\beta}_2 + \varepsilon_{i1928}, \quad (1)$$

where i indexes the firm, Y is an indicator variable that takes the value 1 if a firm in our 1928 sample fails before 1937, *Connections* is the measure of network ties to other firms, and \mathbf{X} is a vector of control variables. In all of our regressions, we include the natural logarithm of one plus the number of directors on the board. This control captures both the mechanical tendency for larger boards to have more connections and any link between board size and effectiveness (Yermack, 1996). We also control for other factors that could affect survival probability and correlate with the network links of firms' executives and directors: firm size (measured by the natural logarithm of total assets), firm leverage (measured as total debt scaled by total assets), firm cash holdings (measured as cash plus marketable securities scaled by total assets), and an indicator that takes the value one if the firm is private. In some specifications, we also include industry fixed effects and fixed effects for all of the states in which firms have offices. We correct standard errors for

heteroscedasticity across firms.¹⁰ In the Online Appendix, we demonstrate the robustness of our results to estimating the effects within a Cox Proportional Hazard Model that explicitly accounts for variation in the timing of failure across firms within the 1928 to 1937 window.

We report the results of estimating Equation (1) in Table 3. In Column 1, we use a continuous measure of *Connections*, the natural logarithm of one plus *TotalConnections*. We confirm a negative and significant correlation between network ties and the likelihood of firm failure (p -value = 0.078). Economically, a one standard deviation increase in network ties predicts a decrease in the likelihood of failure by roughly 1.5 percentage points, a 7.5% decrease from the sample average of 20%. Among the control variables, we find that smaller firms, private firms, and firms with smaller cash stocks are significantly more likely to fail, consistent with the arrival of a large, unanticipated financial shock in 1929. Though we do not find a statistically significant relation between debt levels and failure, the relation is positive. Moreover, we recover a positive and strongly statistically significant relation if we exclude the cash control. Interestingly, we find that firms with larger boards weather the shock better than firms with smaller boards. In more recent data, Yermack (1996) finds evidence that firms with smaller boards perform better than firms with larger boards. The apparent reversal of the result in our sample is consistent with constraints in the director market that prevent some firms from choosing boards of optimal size.

In Column 2 of the table, we measure *Connections* using a binary indicator that equals one for firms with a value of *TotalConnections* greater than the sample median. This approach is less parametric and also more robust to the presence of measurement error in *TotalConnections*. Using this alternative measure, we find a larger effect of network ties on the odds of firm survival. Here, a firm with more network ties than the median firm has a 3.4 percentage point smaller likelihood

¹⁰ Each firm appears only once in the regression sample and in the same year (1928). Thus, serial correlation and time effects are not a concern.

of failure (p -value = 0.022), a 17% decrease from the baseline failure probability. In Column 3, we further saturate the model with indicators for firms in the second, third, and fourth quartiles of the distribution of *TotalConnections*. We find a negative, but insignificant 2.9 percentage point decrease in the likelihood of failure moving from the first quartile (baseline group) to the second quartile. There is an additional 4 percentage point decrease moving to the third quartile from the second, resulting in an overall 6.9 percentage point lower rate of failure in this quartile compared to the baseline, which is significant at the 1% level. The effect of network connections declines moving to the fourth quartile, though the effect in this quartile relative to the baseline is similar in magnitude to the effect in the second quartile. In Section 3.4, we will find that there is strong heterogeneity in the effect of networks in the cross-section. The lack of power in the fourth quartile here appears to be due to low representation of the types of firms in which connections tend to matter the most: small, private, rural, and cash-poor.

Finally, in Columns 4 to 6 of Table 3, we report the results of re-estimating the specifications from the first three columns of the table, but adding industry and state fixed effects as additional controls. The fixed effects capture omitted variation at the industry or state level that might correlate with network ties and also predict better performance following the shock. For example, firms located in states with larger populations might both have more network ties and weather the financial shock better. Because our dataset is one cross-section measured at a single point in time, the fixed effects capture industry and state level factors that are time invariant and time-varying. We find that controlling for these factors has little effect on our estimates and, if anything, strengthens their significance in some specifications.

A potential confounding factor is the quality of the firm at the time of the shock. Connections could correlate positively with firm quality and this underlying quality, rather than

connections themselves, could predict higher survival during the Depression. Alternatively, weaker firms could seek out connections with other firms more aggressively, to the extent that connections increase value, causing us to understate the effect of connections on survival if we do not account for differences in firm quality. We do not include a direct control for performance in our baseline specification because we do not observe the required income statement information for roughly 30% of our sample firms. However, as a robustness check, we replicate Table 3, but include the ratio of net income to assets as an additional control. Despite the noise in the measure, we find that higher profitability strongly increases survival odds, both economically and statistically. But, importantly, the estimated effect of connections is largely unaffected (and, if anything, slightly stronger). We also perform several additional robustness checks. We include controls for firm age and for director expertise. We also control for county-level variation in government policy responses to the crisis and we use major city fixed effects to control for local agglomeration effects. None of these additional factors can explain the effect of connections we estimate in Table 3. Full results are provided in the Online Appendix.

3.2. Local severity of the Great Depression and the Value of Network Connections

Our baseline strategy in Section 3.1 identifies the effect of network connections on firm survival using a single cross-section of observed ten-year failure rates following the financial shock of 1929. Despite our control for performance, it is possible that firms with more network connections are less likely to fail because they differ from less connected firms on some other dimension of firm quality. Moreover, given our focus on a single cross-section, the estimated network effect could reflect those differences in quality rather than differential responses to a common shock. If so, our evidence would be consistent with even a reverse causality interpretation: directors may generally prefer to accept positions on the boards of companies that

they believe are more likely to survive than on the boards of companies that are likely to fail. To confirm the importance of the shock itself and thereby address the concern, we test whether the effect of network connections is stronger in localities in which the impact of the disruptions caused by the Great Depression was more severe. The severity of the shock must not be positively correlated with the unobserved quality of local firms for our approach to be valid.

To implement this identification strategy, we consider variation in the severity of the financial crisis that is due to variation in the county-level rate of bank suspensions during the heart of the Depression. Following Calomiris and Mason (2003) and Nanda and Nicolas (2014), we use data from the Federal Deposit Insurance Corporation (FDIC), which provides county-level annual reports on active and suspended banks and their deposits from 1920 to 1936.¹¹ Because the peak of bank runs and failures occurred between the summer of 1929 and winter of 1933 (Mitchener and Richardson, 2019; Richardson, 2007, 2008; Bernanke, 1983; Calomiris and Mason, 2003), we focus on suspensions that occurred during the 1930 to 1933 window in our analysis. Prior to the Depression, bank loans were a primary source of working capital for the industrial sector (Currie, 1931; Reifer, Friday, Lichtenstein, and Riddle, 1937). Thus, greater local failure rates are a reasonable proxy for differences in the intensity of the financial shock across firms. (In Section 4.1, we provide direct evidence of the importance of disruption to trade credit for firm failure.) Consistent with this view, Nanda and Nicholas (2014) note that “Ford Motor Company provided approximately \$12 million in loans to local banks to avert the crisis” (p. 276). On the other hand, it is unlikely that local bank failure rates positively correlate with the locations of ex-ante higher

¹¹ County-level information on banking deposits for the 1920-1936 period is available online at <http://www.icpsr.umich.edu/icpsrweb/ICPSR/studies/7>. While these data do not distinguish bank failures from bank suspensions, Calomiris and Mason (2003) argue that these shortcomings do not interfere with identifying bank distress empirically. The data are unavailable in the states of Wyoming, Hawaii, and Alaska, and in the District of Columbia.

quality firms (i.e., firms that are more likely to survive independently from network connections). If anything, banks located in areas surrounded by stronger firms might be less likely to fail.

We measure the county-level bank failure rate using total bank deposits in the county that were held in banks that were suspended between 1930 and 1933 as a fraction of county-level bank deposits in 1929. For each firm, we match county bank failure rates to the locations in which the firm has offices, taking the minimum for firms with offices in multiple counties. We then estimate Equation (1) including the local bank failure rate and its interaction with our network measures as additional independent variables. We estimate versions of all of the specifications from Table 3 and report the results in Table 4. Consistent with the discussion above, we find that greater local bank distress is associated with a higher likelihood of firm failure when we include state and industry fixed effects (Columns 4 to 6). We also confirm that the effect of network connections on failure probability is larger in magnitude where a larger fraction of local deposits are held in banks that are in distress. The estimates of the interactive effect of our network connection measures with the bank distress variable are negative in all cases and appear to increase with the number of connections. For example, in Columns 3 and 6, we estimate interactions of -0.29 and -0.27, respectively, with the indicator for connections in the top quartile of the distribution (both statistically significant at the 5% level), compared to interactions of -0.13 and -0.12 for firms with numbers of connections in the second quartile. At the mean of the distress variable (0.13), these estimates imply a decline in the likelihood of failure of roughly 4 percentage points among firms with network ties in the top quartile. However, they also suggest large heterogeneity in the effect of connections. For example, the most distressed counties have bank suspension rates greater than 90%. In such counties, the Column 6 estimates would imply a roughly 26 percentage point lower failure rate among the most connected firms. Overall, the results provide additional evidence in

support of a causal interpretation of the relation between network ties and firm failure and, in particular, confirm the relevance of the financial shock itself for the estimated differences.

3.3. *Instrumental Variables Regressions*

One way to address directly the concern that network ties correlate with an omitted factor that positively predicts firm survival is to construct an instrument for network connections. Our IV strategy relies on two empirical observations. First, director markets were relatively segmented in 1928 (e.g., our sample predates the widespread introduction of commercial air travel in the United States). In the Online Appendix, we demonstrate this segmentation at the regional level within our sample. This pattern implies that most of the demand for directors' services in other firms will be local and that there can be substantial differences in this demand across localities at any given point in time. Second, firms are more likely to choose directors from firms within their own industries.¹² This preference implies that firms located in states in which the number of local directors in the industry is small are likely to have fewer network connections because of a lower local demand for their directors' services. Geographic segmentation in turn implies that the lower local demand is not substituted one-for-one by heightened out-of-state demand.

One reason why there could be low local demand for a director's services within her industry is because the local market is small. However, this source of variation is likely to correlate directly with the chances of survival in a crisis. We instead construct our instrument to exploit variation in local demand that is due to variation in the sizes of the boards of local firms in the industry. We define our instrument *Low* as an indicator variable that takes the value one if the fraction of the directors in the state(s) in which the firm operate(s) that are in the firm's industry

¹² In our data, within-industry directors are roughly equally as common on boards as directors from outside the industry, which is a clear over-representation relative to random assignment among 25 industries.

is in the bottom third of the distribution.¹³ We isolate variation that comes from differences in average board sizes by directly controlling for the number of firms in the state-industry pair (both continuously and as an indicator that, like *Low*, takes the value of one if the number of firms in the state-industry pair is in the bottom third of the distribution).¹⁴ Moreover, we control for the overall number of directors in the state (again continuously and as an indicator for firms located in states in the upper third of the distribution).¹⁵ These controls ensure that it is only the ratio of the number of directors to firms in a state-industry pair that identifies our results. Variation in the total number of directors, which is captured by the additional controls, could again correlate with variation in local market vibrancy. Finally, we add an indicator for firms with board sizes in the lower third of the distribution. The firm's own board size could correlate with the local average board size and, as we see in Table 3, has a weak negative correlation with firm failure. The added control prevents the instrument from absorbing nonlinearities in this effect. Ultimately, our identification rests on the assumption that *Low* is excludable from Equation (1). Failure would require differences between the average board sizes of firms within the same industry across different states, conditional on the full set of covariates in our regressions, to correlate with an omitted factor that predicts firm survival.

¹³ The exact cutoff point is not crucial for our identification. What is key is that we identify the lower portion of the distribution. For example, we find similar results if we instead consider firms in the bottom quartile of the distribution. We also consider using the continuous measure of the local director pool in the industry as the instrument, but it has a weaker correlation with network ties, making it a worse candidate for an IV regression.

¹⁴ Another way to capture local market size is to measure total assets (or sales) within an industry-state pair. As a robustness check, we add these additional controls to our IV regressions. The results are qualitatively similar and the controls themselves are economically and statistically insignificant. Because both variables decrease sample size, we do not include them in our base regressions.

¹⁵ We can identify these controls despite the presence of state fixed effects because some firms operate in more than one state in our sample. We also estimate a specification in which the binary indicator is for firms in the lower third of the distribution with very little effect on the results. A nonlinearity at the upper end of the distribution is more likely to account for the explanatory power of *Low*.

We present the results of implementing our IV strategy in Table 5. Because the instrument varies both within-state and within-industry, we can use it to identify the effect of connections while continuing to absorb (separately) all industry and state level variation with fixed effects. In Column 1, we report the results from the reduced form regression of the indicator for firm failure on the instrument *Low* and our set of controls. We find that the instrument *Low* has a positive and significant effect on the likelihood of failure. Firms located in areas in which their directors have less outside demand for their services are more likely to fail, even controlling for the size of their local product markets. As discussed above, the most obvious threat to the exclusion criterion centers around correlation between *Low* and some notion of local market vibrancy. Importantly, none of the direct controls that we add to capture local market conditions – such as the numbers of firms or directors in the state-industry pair – have any significant explanatory power for the likelihood of failure (even if we exclude *Low* as an explanatory variable), casting significant doubt on the ability of this alternative story to explain our findings. Moreover, our results are robust to the inclusion of major city fixed effects, as defined in Section 3.1, as additional controls.

In Column 2, we report the first stage regression for our instrumental variables strategy using the natural logarithm of *TotalConnections* as the endogenous variable in Equation (1). As predicted, we find a strong negative partial correlation of *Low* with network ties after including the controls. The instrument is strongly statistically significant (p -value < 0.01); however, the first-stage F-statistic of 8.049 lies between the Stock-Yogo (2005) critical values for a test of 15% and 20% size, suggesting some caution in assessing the strength of the instrument. In Column 3, we report estimates from the second stage regression. We find that the instrumented effect of *TotalConnections* is negative and statistically significant (p -value = 0.056). In Columns 4 and 5, we report the results from a similar two-stage least squares system in which the endogenous

measure of network ties is an indicator variable that equals one for firms with a value of *TotalConnections* greater than the sample median. We again find that the instrument significantly predicts *TotalConnections* in the first stage ($p\text{-value} < 0.001$) and that the instrumented effect of network ties on the likelihood of firm failure is negative and statistically significant ($p\text{-value} = 0.025$). Here, the first-stage F-statistic of 20.278 lies comfortably above the Stock and Yogo (2005) threshold for a test of 10% size, suggesting that the instrument is indeed strong.

It is noteworthy that the estimated effect of network ties is substantially larger in magnitude in these regressions than in the baseline regressions in Table 3. One possibility, consistent with the negative correlation between net income and network ties in our sample, is that weaker firms are more likely to seek network ties so that endogeneity attenuates estimates of the network effect in OLS specifications. Hermalin and Weisbach (2003) make a similar argument in the context of board independence. We also observed in Section 3.2 that there is heterogeneity in the effect of networks in the sample and provide additional evidence of this heterogeneity in Section 3.4. Another possibility, then, is that the local treatment effect measured by *Low* applies to a subset of firms in which the effect of network ties is larger than the population effect. We provide additional tests to distinguish these possible explanations from weakness of the instrument in the Online Appendix. Ultimately, given the results from Section 3.2 and the remainder of the paper, the causal interpretation of our results does not rest solely on the validity of the IV approach.

3.4. *The Value of Network Connections for Firms of Different Types*

Our results in Section 3.2 suggest that network ties contribute the most to firm survival where financial constraints are most likely to bind, suggesting a role for connections in easing the flow of financing to constrained firms. Moreover, network ties could facilitate the flow of information about firm or market conditions, leading to more effective adjustment to changing

fundamentals. If so, network connections should have a stronger effect among firms that are otherwise more isolated from information flow. Given this discussion, we test whether network connections are more valuable to information-sensitive and financially-constrained firms. By confirming the specific theoretical patterns predicted by a network effect, these tests can further bolster the causal interpretation of our baseline results. In particular, a potential omitted variable must be able to explain not only the simple positive relation between network links and survival, but also the interacted effects with measures of constraint.

In the 1920s, not only was travel between different geographic markets more difficult, modern forms of communication – such as the internet – had not yet been introduced. Thus, we construct a measure of geographic isolation to capture variation in access to information. We define an indicator variable for rural firms that takes the value of one if the rural population in the counties in which the firm has offices is greater than 60%.¹⁶ We also consider three measures of financial constraint. Most directly, we compare firms that have cash holdings scaled by assets that are above the median in 1928 to firms that have cash holdings below the sample median. Building on the literature on financing constraints, we also compare small to large firms, defining an indicator variable that splits the sample at the median value of total assets. And, we compare private to public firms. The final proxy is likely to capture financing constraints, but also opaqueness and inferior access to information.

¹⁶ We use county-level data on urban population from Fishback, Kantor, and Wallis (2003), available at <https://www.openicpsr.org/openicpsr/project/101199/fcr:versions/V1/New-Deal-Spending&type=folder> to construct the rural measure. Our results are similar if we increase the threshold from 60%, though the proportion of firms classified as rural quickly diminishes. If we decrease the threshold to 50%, we find results that are similar in magnitude, but not statistically significant. We also measure rural population at the state level using data on urban population from the U.S. Census Bureau's website: <https://www.census.gov/population/censusdata/urpop0090.txt>. Urban states under this classification scheme are California, Connecticut, Illinois, Massachusetts, Maryland, Michigan, New Jersey, New York, Ohio, Pennsylvania, and Rhode Island. The District of Columbia also counts as an urban area. Under this definition, we find similar results, though the state-level classification results in a higher fraction of "rural" firms in the sample.

In Table 6, we report the results from augmenting the linear probability model in Equation (1) individually with each proxy for information sensitivity or financing constraints and its interaction with network ties. To measure network ties, we use the indicator variable that takes the value one if the firm has *TotalConnections* greater than the sample median. Focusing on Columns 1 to 4 of the table, we find that the three measures of financial constraint – *Small Firm*, *Private*, and *Low Cash* – are each significant positive predictors of firm failure following the financial shock in 1929. Firms that we identify as financially constrained have a likelihood of failure that is larger by 7.6 to 10.8 percentage points, consistent with our interpretation of the measures. Turning to the interactions, in all cases we find a significant negative interaction with network ties. Economically, membership in the high connections subsample erases the effect of financial constraints on firm failure using all three measures (i.e., we cannot reject the hypothesis that the coefficient estimates on financial constraint and its interaction with connections sum to zero). We do not find that rural firms have a different likelihood of failure from firms located in urban states (Column 2). However, we find a significant negative interaction effect with network ties. Firms in rural areas that are members of the high connections subsample have failure rates roughly 12 percentage points lower than other firms.

In Columns 5 to 8, we repeat the regressions, but include state and industry fixed effects, with little qualitative effect on the results. We also find broadly similar patterns if we use our instrument for network connections, running separate two-stage least squares estimations on subsamples defined by each proxy for constraint. In all cases, we find estimates of the effect of network ties that are larger in magnitude among firms we classify as constrained. In two cases (*Private* and *LowCash*), we find significant instrumented effects of network ties only within the constrained subsample. Finally, we isolate firms that are less than five years old as an alternative

measure of constraint. Though the estimates are weaker economically and statistically, we do observe that younger firms are generally more likely to fail and that network links reduce the effect.

4. Economic Mechanisms

Director and executive network connections to other firms predict increased odds of survival through the Great Depression, particularly among firms that are likely to experience financial constraints at the time of the shock. Next, we provide additional analysis to identify the economic mechanisms through which connections aid industrial firms. First, we test whether managerial connections facilitate firm-to-firm lending via trade credit. Second, we explore the possibility that connections help firms to coordinate their pricing policies with product market competitors. Third, we test whether banker-directors with direct links to financial institutions are responsible for the effects. Fourth, we test whether network ties more generally capture better links to financial centers. Finally, we test whether connections increase the likelihood that firms receive equity investments from other industrial firms. By identifying additional patterns that an omitted variable would have to explain, but that follow naturally from a causal link between networks and firm survival, this analysis further addresses potential endogeneity of the network measures.

4.1. Trade Credit

One channel through which network ties could improve firms' resilience during a financial crisis is by facilitating the extension of favorable trade credit terms between firms with customer-supplier relationships. Pre-existing network connections can be a way to lower the information asymmetries that could otherwise make such lending excessively costly. In addition, a pre-existing trading relationship between the borrowing and lending firms can increase the marginal benefit to the lender of providing financial assistance during a time of crisis in order to avoid a costly search for new trading partners. Nanda and Nicholas (2014) document the dependence of the automobile

industry in Detroit on local banking during the 1930s. More generally, their evidence suggests that working capital from trading partners could be particularly important to small, financially constrained firms when local bank financing is scarce, consistent with our results in Section 3.

To test for evidence of the trade credit channel in our data, we exploit variation in the financial conditions of the firm(s) to which sample firms are connected. To begin, we distinguish between connections to firms that are cash-rich (i.e., have cash holdings as a fraction of total assets that are higher than the sample median) and connections to firms that are cash-poor. In Table 7, we report the results from estimating Equation (1) using separate variables to capture connections to cash rich and cash poor firms. Mirroring the specifications in Table 6, we compare the survival rates of firms with levels of each type of connection that are above and below the sample median. In Column 1, we include connections to cash-rich firms as the independent variable of interest. We find that such connections have a strong negative effect on the likelihood of firm failure that is statistically significant at the 1% level. Economically, the effect is roughly 50% bigger than the effect of having an above-median level of total connections on failure, as reported in Column 2 of Table 3. In Column 2, we report the results using connections to cash-poor firms to define the independent variable of interest. Here instead we do not find any significant effect of connections on the likelihood of firm failure, though the effects of all other included independent variables are similar to the estimates in Column 1. In Column 3, we report estimates from a regression including both the measure of high connections to cash-rich and cash-poor firms. We again find a strong negative effect of connections to cash-rich firms on failure. The small negative effect of cash-poor connections we report in Column 2 does not survive when we also include the measure of cash-rich connections, suggesting that it is an artifact of positive correlation between the two measures.

In Columns 4 to 6, we report the results from replicating the Columns 1 to 3 regressions with the addition of state and industry fixed effects. As in prior tables, our results are largely unchanged.

Building on this evidence, we test in Table 8 whether the effect of connections to cash-rich firms on survival is particularly prominent among firms that we classify as financially constrained. We consider all three measures of financial constraints from Table 6: firms with low cash holdings, private firms, and small firms. We report the results of separately estimating the regression specification from Column 6 of Table 7 (i.e., including both connections to cash-rich and cash-poor firms in Equation (1) along with state and industry fixed effects) in the subsamples of financially constrained and unconstrained firms for each measure of constraint.

In Columns 1 and 2 of Table 8, we report the results using firm cash holdings as the measure of financial constraints. In Column 1, we find that connections to cash-rich firms indeed have a strong negative effect on the likelihood of firm failure among cash-poor (constrained) firms, but connections to cash-poor firms again do not have a significant effect. By contrast, we see in Column 2 that neither type of connection has a significant effect on the likelihood of firm failure among cash-rich (unconstrained) firms. In Columns 3 and 4, we report the results for private (constrained) and public (unconstrained) firms. And, in Columns 5 and 6, we do the same for small (constrained) and large (unconstrained) firms. In both cases, we find the same pattern: connections to cash-rich firms are a significant predictor of firm survival following the financial panic, but only among constrained firms. Connections to cash-poor firms never have a significant effect on the likelihood of firm failure. We do not observe a similar pattern if we split the sample into firms located in urban and rural areas, a partition with a less obvious relation with financial constraints.

Given the relation between enhanced survival among low-cash firms and the cash holdings of connected firms, we dig deeper into the role of working capital financing as a potential channel

for the effect. Specifically, we test for direct evidence that it is connections to firms that report increased accounts receivable during the crisis years that correlate with reduced failure rates. To perform this test, we collect information on accounts receivable for each sample firm from the 1928 and 1934 Moody's manuals and compute log changes for each firm.¹⁷ Because 1933 was near the nadir of the Great Depression, we unsurprisingly observe an average decrease in both accounts receivable and accounts payable between the two observations. We observe positive changes in roughly the top quartiles of the distributions of both variables. Thus, we define firms with high changes in receivables to be firms in the top quartile of the distribution (and, later, likewise for payables). We then construct two indicator variables to identify firms with above-median connections to firms with high changes in receivables and above-median connections to firms with low changes in receivables. It is important to note that we only observe the necessary data to compute changes in receivables for roughly 56% of the firms in our sample. We do not include connections to firms with missing trade credit data in either category.

In Table 9, we report estimates of Equation (1) using the measures of connections to firms with high and low changes in receivables as the key independent variables. The specifications exactly mirror those we reported in Table 7 to measure the effects of connections to cash-rich and cash-poor firms. We find that it is indeed connections to firms that increased accounts receivable that significantly predict a lower likelihood of failure, whether we consider them independently or together with connections to firms that reduced receivables. There is no appreciable effect of connections to firms that did not increase receivables on the likelihood of firm failure.

¹⁷ Accounting data, even when available, is not reported in a standardized way across firms. For example, one firm might report "Accounts Receivable," while another reports "Accounts and Notes Receivable" or some other variation. We collect the item most closely resembling accounts receivable for each firm. We verify that individual firms generally maintain a consistent reporting convention over time, so that changes over time are measured meaningfully.

We conduct several additional tests to explore the nature of the trade credit channel. First, we replicate the Table 9 specifications using changes in accounts payable rather than accounts receivable to partition connections. As with receivables, it appears to be connections to firms that increase payables during the Depression that are associated with lower failure rates, but the magnitude of the estimates is smaller than the effect of receivables and none are statistically significant. Though short term funding through increased receivables appears to be the most important to reduce the odds of failure, the results together are consistent with cash-rich firms stepping into the void left by failing banks more generally to intermediate the flow of working capital among industrial firms. As a second step, we test whether trade credit flows are indeed responsible for the effect of cash-rich connections on failure that we measured in Table 7. To do so, we further partition connections to firms with high changes in accounts receivable into those that are cash-rich and cash-poor (following the definitions from Table 7) and likewise for connections to firms with low changes in receivables. We then define four indicator variables for firms with above-median numbers of connections in each of the implied categories (cash-rich high change in receivables; cash-poor high change in receivables; cash-rich low change in receivables, cash poor low change in receivables). In Table 10, we report the results of estimating Equation (1) including combinations of these measures of connections. When all four types are included together, we confirm that it is connections to cash-rich firms that also increase accounts receivable during the crisis that significantly predict a reduced likelihood of failure. None of the other types of connections predict failure, economically or statistically. As in prior tables, the results are robust to the inclusion of both our typical set of controls and state and industry fixed effects.

As a final test, we directly analyze changes in (the natural logarithm of) the ratio of accounts receivable to accounts payable between 1928 and 1933. This measure allows us to capture

changes in the relative intensity with which firms are net providers or recipients of trade credit during the crisis. To begin, we regress the measure on our standard set of control variables (including industry and state fixed effects) as well as the natural logarithm of the ratio in 1928, prior to the shock.¹⁸ The independent variables of interest are an indicator for above median numbers of network connections and its interaction with an indicator for firms with below-median 1928 cash holdings. We report the results in Column 1 of Table 11. We find a pattern consistent with the inter-firm lending channel. We find that high-cash firms increase their provision of working capital (the estimate of the level effect of high connections is positive and statistically significant at the 10% level). However, low-cash firms decrease their provision of working capital by roughly the same magnitude. The difference-in-differences between the two groups is roughly 25% of a standard deviation of the dependent variable and is statistically significant at the 5% level. In Column 2, we isolate further the role of cash-rich firms in providing working capital to cash-poor trading partners, the lynchpin of the trade credit mechanism. To do so, we focus on the subsample of firms with 1928 cash holdings above the sample median. Within this subsample, we regress the change in the trade credit balance on indicators for above median numbers of connections to cash-rich and cash-poor firms (along with the full set of controls from Column 1). We do not observe a difference in the change in the trade credit balance for firms connected to cash-rich firms relative to their peers; however, we observe a significant increase in the provision of trade credit among cash-rich firms that disproportionately have connections to cash-poor firms.

Overall, our tests suggest that one mechanism through which director and executive network links reduce the probability of firm failure is by facilitating access to finance through trade credit channels.

¹⁸ The 1928 ratio between accounts receivable and payable is nearly uncorrelated with our connections measure, so that including this control is not critical for our inferences.

4.2. *Product Market Collusion*

Another mechanism through which director and executive connections could increase survival odds through the crisis is by facilitating price coordination in product markets. Competing firms that sell in the same markets could collude to keep prices high in order to stave off failure. If this is the case, then the effect of connections on survival should be strongest for connections to firms in the same state and industry because collusion is most beneficial when firms sell the same product to the same customers. Thus, we test whether executive and director connections have a greater effect on survival if they are to firms that operate in the same industry or state.

In Columns 1 to 3 of Table 12, we report the results of estimating Equation (1), using indicator variables that measure above-median numbers of connections to firms within and outside the industry as independent variables of interest. For brevity, we report only specifications with state and industry fixed effects. Consistent with the theory, we find that it is indeed connections to firms inside the industry and not outside the industry that increase the odd of survival. Firms for which the number of within-industry network connections exceeds the median have a 5.7 percentage point lower failure rate during the Depression. Above-median levels of out-of-industry connections, on the other hand, do not significantly affect the likelihood of survival. We perform a similar test in which we measure separately the effects of connections to in-state and out-of-state firms. Here, we do not find strong evidence that the effect of network ties on survival differs depending on whether the connection is to an in-state or out-of-state firm (though the point estimate on an indicator for above-median in-state connections in our baseline specification is generally larger in magnitude than the estimate for out-of-state connections).

Given our definitions of industry groups, our evidence that connections within the group have more of an effect on survival is also consistent with the trade credit channel. For example, we define the Oil industry group using search strings that include “gasoline,” “crude,” and “refin.”

In this case, firms from the entire supply chain, stretching from extraction to retail sales, are part of the industry group. To separate the potential effect of price collusion from the effects of trade credit, we distinguish between within-industry connections to firms located in-state and out-of-state. We report the results in Columns 4 to 6 of Table 12. We find that above-median numbers of connections to within-industry firms located out-of-state significantly predict a lower failure probability, while above-median connections to within-industry firms located in-state does not. While not obviously consistent with the collusion channel, this result can be reconciled with the trade credit channel if customers and suppliers do not necessarily collocate in the same markets or if the effect of the financial shock is not identical across states. In Columns 7 to 9 of Table 12, we report the results of interacting industry connections with the cash holdings of the connected firm. We confirm that above-median connections to high-cash firms within-industry predict heightened survival. Above median connections to high-cash firms out-of-industry do not (nor do above median connections to low cash firms of either type). We also find some evidence that it is above-median connections to high-cash firms out-of-state that particularly matter, though here the cross-group differences are not statistically significant. Taken together, this evidence, though indirect in nature, suggests that the disproportionate impact of within-industry ties may be additional evidence of the extension of favorable trade credit terms between connected firms on the same supply chains rather than evidence of price collusion.

4.3. *Links to Financial Institutions*

Another possibility is that the shared directors we observe in our sample are actually banker-directors who aid the firm directly by facilitating access to financial markets. For example, Frydman and Hilt (2017) find evidence that firms with underwriters on their boards had cheaper access to finance and higher investment rates in the early twentieth century. Though they argue

such directorships were most common among railroads, it is possible that a similar mechanism could have aided industrial firms during the Depression. We take two approaches to assess the likelihood that this mechanism could drive our results. First, we recalculate our measure of connections excluding cases in which the connection comes via an individual whom we only observe as a director in the 1928 Moodys' Industrial Manual. Moody's published a separate volume that provided financial and management information for banks (and another for railroads). Thus, we can be sure that individuals we identify as managers are not bankers. Second, we restrict our sample only to firms that did not have any outstanding bank debt or mortgages in 1928. The results in Table 6 show that our results are strongest among private firms. Thus, the most plausible concern is that the connections driving our results come from shared commercial bankers who serve on the boards to facilitate bank lending. We find that neither restriction has a material effect on our results. In Online Appendix Table 6, we present the estimates of regressions that impose both additional conditions. We continue to find that connections significantly decrease failure rates among private, rural, cash poor, and small firms. If anything, the point estimates are larger in magnitude, suggesting it is unlikely that the presence of banker-directors drives our results.

4.4. *Links to Financial Markets*

It is also possible that connections to industrial firms correlate with connections to financial centers, so that our estimates pick up the effects of greater financial access through public markets. One way to test for this mechanism is to measure directly the frequency with which director network connections are to firms located in major financial centers. For each firm, we count connections to firms in each city with an active stock market in the 1920s: New York, Chicago, Boston, Philadelphia, Baltimore, Cincinnati, Detroit, Cleveland, Hartford, Honolulu, Los Angeles, Louisville, Pittsburgh, San Francisco, and St. Louis. We then measure the effect of connections to

firms in these cities within our baseline regression specifications from Table 3. We do not find any evidence that connections to firms in these specific cities are particularly important for firm survival. We also consider the effects of more prominent markets individually and as a subgroup: New York, Chicago, Boston and Philadelphia. We again do not uncover any evidence that it is connections to firms in these markets that drive the effect of connections on survival.

4.5. *Equity Stakes*

Another way that firms could provide financial assistance to troubled peers in addition to providing firm-to-firm credit is by taking equity stakes. Executive and director network ties could lower the costs of such investments by reducing the information asymmetries between firms. In particular, the information that flows through such connections could aid firms in distinguishing between potential targets that are in financial and economic distress during the crisis.

To explore this channel, we test whether network connections affect the probability that a firm becomes a takeover target or merges with another firm during the Depression. Takeovers are the limiting case of cross-firm equity investments, but have the advantage of being readily observable. Though they are also a mechanism through which firms “disappear” from the marketplace, we analyze acquisitions separately from closures because our prediction for the direction of the effect of network ties is opposite in the two contexts.

We use a variant of the linear probability model in Equation (1) to test whether network ties increase the likelihood that a firm is acquired during the Great Depression. In this case, the dependent variable is an indicator variable that takes the value of one if the firm is acquired or merged with another firm before 1938. Otherwise, we mirror the regression specifications from our analysis of firm failure in Table 3, including the same controls and network measures. We report the results in Table 13. In Column 1, the measure of network ties is the natural logarithm of

one plus *TotalConnections*. In Column 2, we use an indicator variable that takes the value of one if the firm has more network connections to other firms than the median firm in the sample and in Column 3 we include indicator variables for the top three quartiles of the distribution of connections. Generally, we find that more network ties indeed increase the likelihood that a firm is acquired or merges with another firm following the shock to financial markets in 1929. The economic magnitudes are somewhat larger than the effect of network connections on the likelihood of firm failure, though opposite in sign. A modest difference is that the effect on acquisitions appears to come primarily from the comparison of firms in the top three quartiles of the distribution of connections to firms in the bottom quartile. We do not observe significant differences across the top three quartiles. In Columns 4 to 6, we repeat the regressions from Columns 1 to 3, but including additional controls for state and industry effects. The results are similar, though state and industry controls yield estimates of the network effect that are modestly larger.¹⁹

As in Table 6, we test whether the effect on the likelihood of being acquired is magnified within small, cash-poor, rural, or private firms. We present the results in the Online Appendix. In general, we do not uncover any consistent relation between financial constraints and the effect of network ties on the likelihood of being acquired. When we use the most direct measure of financial constraints, low cash holdings, the estimate of the interaction effect is statistically insignificant and near zero. We find similar results when we use firm size as the proxy for financial constraints. We also do not find any evidence that the positive correlation between network ties and the

¹⁹ We also reexamine the evidence within a two-stage least squares framework using the instrument *Low* from Section 3.3. Though the first stage regressions are identical to the ones we report in Table 4, here we do not find any significant effects of network ties on the likelihood of acquisition or merger in the second stage regressions. Thus, caution is warranted in the interpretation of the findings. One possibility is that network ties cause an increase in the likelihood of acquisition during crisis times because they facilitate the flow of information to potential acquirers. Another possibility is that the positive correlation in Table 12 comes from selection: weaker firms choose directors with more network ties and are also more likely to fail and be purchased during the Depression. Note however that to the degree that potential omitted factors that could predict firm failure and the probability of being acquired overlap, the failure of the IV here mitigates concerns about weakness of the instrument leading to inflation of the estimates in Section 3.3.

likelihood of being acquired is concentrated among firms located in states with larger rural populations. However, we do find that the positive effect of network connections is concentrated among private firms. The effect is particularly strong, economically and statistically when we include state and industry fixed effects. These results are consistent with the role of connections in facilitating information flow about opaque firms to potential acquirers, but, surprisingly, do not suggest that the mechanism is more or less active among firms that are financially constrained.

Overall, our evidence points to the increased flow of trade credit as a key economic channel through which executive and director connections help financially constrained firms to survive through the Depression. We also observe some evidence that network connections facilitate equity investments, but the effects are not concentrated among financially constrained firms. Nevertheless, it is important to note that these and other potential economic mechanisms are not mutually exclusive. In particular, there may be other conduits through which connected industrial firms can aid troubled peers – such as partial equity stakes or direct long-term loans – that we do not observe directly in our data.

5. Conclusion

We study how network connections to other firms through executives and directors affect firm outcomes during a major financial shock. We find that firms with more network ties in 1928, on the eve of the Great Depression, are more likely to survive over the following 10 years.

Among the advantages of our historical setting is that both financial and director markets were more segmented than they are today. We exploit plausibly exogenous variation across these local markets to mitigate the identification challenge posed by the endogeneity of director network links. Following the banking literature (e.g., Nanda and Nicholas, 2014), we show that connections have a stronger positive relation with survival probability in local markets in which a greater

fraction of banks entered distress during the peak crisis years of 1930 to 1933. We also show that the portion of the variation in network ties that is predicted by differences in the local demand for directors' services outside the firm – conditioning on the vibrancy of the local market – is sufficient to identify our results. As a third way to address the concern that network ties could be correlated with an omitted factor that predicts firm survival, we test whether connections indeed matter the most among firms that are likely to be the most vulnerable to a financial shock. We find that the effect is indeed particularly pronounced among financially constrained firms – small firms, private firms, and firms with low cash holdings – as well as among firms located in rural areas.

We also investigate a variety of mechanisms that could explain our baseline finding. Our evidence suggests that network ties are particularly important to facilitate the flow of trade credit from financially healthy firms to constrained trading partners. We find not only that it is connections to cash-rich firms that mainly drive our results, but that, in particular, it is connections to cash-rich firms that also increase their accounts receivable between the peak crisis years that predict higher survival rates. The evidence suggests that network links allow firms to distinguish between unviable firms and firms that are constrained by the shock, but economically sound. This information allows them to profitably perform an intermediation function that is normally done by commercial banks. Thus, our results provide a novel link between the literature on director networks and the literatures on trade credit and cash holdings. In the latter case, our findings could help to resolve the puzzle of large corporate cash holdings despite their tax disadvantages. In addition to providing precautionary savings, cash enables firms to extend working capital to trading partners in times of crisis. The effects on failure rates are significant – our analysis suggests that high connections reduce the likelihood of failure by roughly 20%. In turn, cash-rich firm can avoid disruption due to the loss of trading partners as well as the costly search for new partners.

More generally, our evidence suggests that network ties can provide some stabilization of the economy in times when credit markets freeze up, preventing the failure of firms that are viable except for the bad fortune of lacking financial resources at the time of the shock. Such a backstop could be particularly important to the degree that firm failures result in layoffs that further depress local demand, producing the potential for additional feedback effects. Thus, policies regarding board composition and corporate governance can affect not only individual firms, but also can have a multiplier effect through networks. In this sense, our results suggest a partial counterargument to the conventional wisdom in the governance literature that “busy” CEOs and directors who serve as directors on multiple boards are bad for firm value. Moreover, our analysis questions the policy prescriptions of the literature on “interlocked directorship.” That literature suggests benefits from restricting firms’ ability to choose board members. Our results instead suggest that limiting firms’ abilities to construct optimal networks could also limit the effectiveness of networks as a stabilizing mechanism in response to common shocks.

Figure 1. The figure presents a graphical representation of the network of directors and executives in the sample of industrial companies from the 1928 Moody's Industrials manual. Subsidiaries and foreign companies are excluded from the network. The diagram does not include 746 firms that do not have any connections to other firms, though they are included in the analysis. The representation is an energy diagram created using the 2D Fruchterman-Reingold algorithm. Colors indicate firms that survived until 1937 (green) and firms that did not (red).

Table 1
Summary Statistics

The sample consists of firms from the 1928 volume of the Moody's Industrials manual, excluding foreign firms and subsidiaries. All variables are measured as of 1928, except where indicated. Rural is an indicator variable equal to one for firms that have offices only in counties in which the rural population in 1930 is greater than 60%. Total Connections is the sum of connections to other firms in the sample via shared directors or managers. In measuring Connections to High (Low) Cash Firms, High Cash Firms are firms with Cash/Assets above the sample median value. Low Cash Firms are the complementary set of firms with values below the sample median. Connections to firms for which Cash/Assets is unavailable are not included in either group. Total assets are reported in \$1000.

	Observations	Mean	Median	Standard Deviation
<i>Panel A. Main Control Variables</i>				
Total Assets	3024	16,029	4,259	68,924
Cash/Assets	2992	0.086	0.049	0.1

Table 3
Network Connections and Firm Failure

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm does not survive to 1937. Total Connections is the sum of connections to other firms in the sample via shared directors or managers. Total Connections > Median is an indicator variable equal to one for firms that have a value of Total Connections greater than the sample median. Total Connections Quartile 2 (3/4) is an indicator variable equal to one for firms that have a value of Total Connections in the sample 2nd (3rd/4th) quartile. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 4
Network Connections and Firm Failure by Local Bank Distress

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm no longer exists in 1937. Total Connections is the sum of connections to other firms in the sample via shared directors or managers. Total Connections > Median is an indicator variable equal to one for firms that have a value of Total Connections greater than the sample median. Total Connections Quartile 2 (3/4) is an indicator variable equal to one for firms that have a value of Total Connections in the sample 2nd (3rd/4th) quartile. Private is an indicator variable equal to one for firms without publicly traded equity. Dep. Susp. is the minimum fraction of county bank deposits as of 1929 in banks that were suspended from 1930 through 1933 among the counties in which the firm has offices. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 5
Network Connections and Firm Failure: IV Regressions

Coefficient estimates in Column (1) are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. Coefficient estimates in Columns (2) and (3) and, separately, (4) and (5) are from two-stage least squares systems of regressions. The dependent variable in Columns (1), (3), and (5) is Disappeared by 1937, an indicator variable that takes the value one if the firm does not survive to 1937. The dependent variable in Column (2) is the natural logarithm of one plus Total Connections. Total Connections is the sum of connections to other firms in the sample via shared directors or managers. The dependent variable in Column (4) is an indicator variable equal to one if the firm has a value of Total Connections greater than the sample median. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Small Board is an indicator variable equal to one if the firm's number of directors is less than the sample 33rd percentile. Few Local Firms is an indicator variable equal to one if the number of firms in the firm's state-industry pair is less than the sample 33rd percentile. Local Firms is the number of firms in the firm's state-industry pair. Many Local Directors is an indicator equal to one if the number of directors in the firm's state-industry pair is above the sample 66th percentile. Local Directors is the number of directors in the firm's state. The instrument Low is an indicator variable equal to one if the number of directors in the firm's industry-state pair as a fraction of the number of directors in the state is less than the sample 33rd percentile. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 6
Network Connections and Firm Failure by Firm Characteristics

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm does not survive to 1937. Total Connections > Median is an indicator variable equal to one for firms that have a value of Total Connections greater than the sample median, where Total Connections is the sum of connections to other firms in the sample via shared directors or managers. Private is an indicator variable equal to one for firms without publicly traded equity. Rural is an indicator variable equal to one for firms that have offices only in counties in which the rural population in 1930 is greater than 60%. Low Cash (Small Firm) is an indicator variable equal to one for firms that have Cash/Assets (Total Assets) less than the sample median. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 7
Network Connections to Cash Rich Firms and Firm Failure

This table shows the relation between a firm's connections to cash rich vs. cash poor firms and firm failure. Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm does not survive to 1937. CashRichConnections (CashPoorConnections) > Median is an indicator variable equal to one for firms that have a value of Connections to High Cash (Low Cash) Firms greater than the sample median, where Connections to High Cash (Low Cash) Firms is the sum of connections to firms with Cash/Assets greater than (less than) the sample median via shared directors or managers. We do not count connections toward either total for cases in which shared directorship or management is observed but Cash/Assets in the connected firm is unobserved. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 8
Network Connections to Cash Rich Firms and Firm Failure by Firm Type

This table shows the relation between a firm's connections to cash rich vs. cash poor firms and firm failure for different sub-samples of firms. The full sample is the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. In column 1 (2), we limit the sample to firms with Low Cash (High Cash) holdings, where High Cash (Low Cash) are firms with Cash/Assets ratios above (below) the sample median. In column 3 (4), we limit the sample to Private (Public) firms, where Private firms are firms without publicly traded equity. In column 5 (6), we limit the sample to Small (Large) firms, where Small (Large) firms are firms with Total Assets below (above) the sample median. Coefficient estimates are from ordinary least squares regressions. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm does not survive to 1937. CashRichConnections (CashPoorConnections) > Median is an indicator variable equal to one for firms that have a value of Connections to High Cash (Low Cash) Firms greater than the sample median, where Connections to High Cash (Low Cash) Firms is the sum of connections to firms with Cash/Assets greater than (less than) the sample median via shared directors or managers. We do not count connections toward either total for cases in which shared directorship or management is observed but Cash/Assets in the connected firm is unobserved. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 9**Network Connections and Firm Failure: By Changes in Connected Firm Accounts Receivable**

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm no longer exists in 1937. HighChgRecConnections (LowChgRecConnections) is an indicator variable equal to one for firms that have a value of Total Connections to firms with high changes in Accounts Receivable between 1928 and 1933 above (below) the sample median, where Total Connections is the sum of connections to other firms in the sample via shared directors or managers and high changes in Accounts Receivable are changes in the top quartile of the sample distribution. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 10**Network Connections to High vs. Low Change in Receivable Firms and Firm Failure by Cash Holdings**

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm no longer exists in 1937. CashRichConnections (CashPoorConnections) are TotalConnections to firms that are Cash Rich (Cash Poor). Cash Rich (Cash Poor) Firms are firms with Cash/Assets greater than (less than or equal) the sample median. Total Connections are links between firms via shared executives or directors. ChgReceivables is the change in accounts receivable reported in the connected firm between the 1928 and 1934 manuals. Q1 indicates the top quartile of the sample distribution. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 11**Change in Accounts Receivable/Accounts Payable by Connections and Cash Status**

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is the change in the natural logarithm of the ratio of accounts receivable to accounts payable from 1928 to 1933. Total Connections > Median is an indicator variable equal to one for firms that have a value of Total Connections greater than the sample median, where Total Connections is the sum of connections to other firms in the sample via shared directors or managers. CashRichConnections (CashPoorConnections) > Median is an indicator variable equal to one for firms that have a value of Connections to High Cash (Low Cash) Firms greater than the sample median, where Connections to High Cash (Low Cash) Firms is the sum of connections to firms with Cash/Assets greater than (less than) the sample median via shared directors or managers. Private is an indicator variable equal to one for firms without publicly traded equity. Low Cash (High Cash) is an indicator variable equal to one for firms that have Cash/Assets less than (greater than) the sample median. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 12
Network Connections to Within vs Outside Industry Firms and Firm Failure

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm no longer exists in 1937. WithinIndustryConn (OutsideIndustryConn) > Median is an indicator variable equal to one for firms that have a value of Connections greater than the sample median, where Connections is the sum of connections to firms within (outside) the firm's industry via shared directors or managers. We do not count connections toward either total for cases in which shared directorship or management is observed but industry of the connected firm is unobserved. WithinIndustryConn_and_ "X" (WithinIndustryConn_and_ "notX") > Median captures connections that are both within industry and also satisfy (do not satisfy) an additional "X" condition. In Columns 4-6, the "X" ("notX") condition is that the firm's connection has to be also through executives and directors who are at firms operating in the states where the firm operates (where the firm does not operate). In Columns 7-8, the "X" ("notX") condition is that the firm's connection has to be also through executives and directors who are at Cash Rich (Cash Poor) firms. Cash Rich (Cash Poor) Firms are firms with Cash/Assets greater than (less than or equal to) the sample median. Similar to WithinIndustryConn > Median, WithinIndustryConn_and_ "X" (WithinIndustryConn_and_ "notX") > Median is an indicator variable for firms with connections greater than the sample median. OutsideIndustryConn_and_ "X" > Median is defined similar to the WithinIndustryConn_and_ "X" > Median. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

[illegible]

Table 13
Network Connections and the Likelihood of Firm Being Acquired

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is Acquired by 1937, an indicator variable that takes the value one if the firm is acquired by another firm by 1937. Total Connections is the sum of connections to other firms in the sample via shared directors or managers. Total Connections > Median is an indicator variable equal to one for firms that have a value of Total Connections greater than the sample median. Total Connections Quartile 2 (3/4) is an indicator variable equal to one for firms that have a value of Total Connections in the sample 2nd (3rd/4th) quartile. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Data Appendix for “Friends during Hard Times: Evidence from the Great Depression”

In this appendix we provide details on the construction of the director network database, as well as the definitions of the industry, geographical and other cross-sectional variables used in our analysis. In section 1 we discuss how we obtain information on firms’ executives and directors from the 1928 Moody’s Industrials manual using OCR and natural language processing techniques. In section 3 we discuss other data that we automatically retrieve from the same manual, such as geographical location and industry information. In section 2 we discuss variables we obtain manually from the 1928 and 1938 Moody’s Industrials manuals.

1 Data on Executives and Directors from the 1928 Moody’s Industrials manual

The main source for our analysis is the 1928 Moody’s Industrials Manual. The manual was the major source of information for industrial firms existing at the time. We run Optical Character Recognition (OCR) on the images of the manual, using “ABBYY FineReader” as the software package of choice. Our main data source is the text output from this OCR stage.

The Moody’s firm-level information is roughly organized as follows:

- (a) Firm title (in capitals), followed by an entry in parenthesis specifying if the firm is a subsidiary of another firm (in parenthesis, using “Controlled by” or “Affiliated with”).
- (b) Details on firm history, from the time it was founded until the year the manual is published.
- (c) Management and board of directors information. This includes the names of officers and directors as well as their geographic location.
- (d) Firm offices location, auditors, day of annual meeting.
- (e) Financial and operating data such as income statement and balance sheet.
- (f) Securities ratings. In particular, the manual provides fixed income security ratings in all years and also equity ratings.
- (g) Business and products. The manuals give detailed information on the business lines and different products marketed by the companies.
- (h) Exchange where the stocks are listed.

The focal point of our research is item (c) above, for which we detail our data gathering efforts below. We also use items (d), (e), and (h) in our analysis and describe the data gathering process for those items in the next sections. While the quality of the images of the 1928 Moody’s

Industrials manual is quite high, the OCR has some non-trivial typographical errors in its output. As a first step in our analysis, we perform an “OCR typo correction” focused on strings of interest, in particular, strings that define sections in the document in which we are particularly interested (i.e. the management and directors section). The code generates flags for pages where the OCR may be corrupted due to image errors, and in those cases we enter/fix the data manually (about 2% of the pages required some manual intervention).

Figure 1 presents the image of the first page of the manual that provides firm-level data. Firm-level data follows a long introduction that includes different indexes and other aggregate data. Figure 1 is a typical entry for a large firm, for which the Moody’s manual devotes multiple pages. Figure 2 presents page 2892 of the manual, which is a typical page for small firms. Note how in this page we have data on five firms: Munson Steamship Line (entry that starts on page 2891), Murphy Varnish Co., Mutual Chemical Co. of America, Mutual Stores Inc., and Myers (F.E.) & Bro. Co. There is significant variation in the scope of coverage, but note how all companies list their management team, board of directors, as well as office location.

For a given firm, we obtain information on the management and board of directors by selecting the entries in the Moody’s manual that follow the string “MANAGEMENT,” or strings that in the OCR output are close to “MANAGEMENT” (e.g. “MGNAGEMENT”). We use natural language processing techniques to parse the text into a database, which involves both typo correction techniques, as well as Named Entity Recognition algorithms. In this step, we obtain the names of each manager and director associated with a given firm as well as their geographic location. Table 2 presents a list of the first few firms appearing in the manual and of their directors, together with location information, from the 1928 Industrials manual. We obtain similar information on the firms’ management and combine the management and director information for each firm, eliminating duplicate observations for people who appear as both executives and directors. We use this list to construct the network.

2 Firm Accounting, Survival and M&A Information

We obtain data on balance sheet and income statement variables from the 1928 Moody’s Industrials manual by hiring research assistants who manually inputted each firm’s information. To identify private firms, we collect information on exchanges where firms list their equity shares. Firms with no listed equity are defined as private firms.

To define our main dependent variables on future survival and M&A status of firms in the 1928 Moody’s Industrials manual, we obtain information on reasons for firm exit from the Moody’s manual coverage. Specifically, the 1938 Moody’s Industrials manual contains the list of “ADDITIONAL U. S. AND CANADIAN COMPANIES FORMERLY INCLUDED”, which provides the list of companies which appeared in previous editions (1928–37) of the Industrials Manual but have been dropped as well as the reason for dropping coverage. Figure 3 shows an example of the list (its first page).

We use this list to determine firms from the 1928 Moody’s Industrials manual that were dropped from coverage and to identify the reason for the exit. We define our key dependent variables as follows. The indicator variable “Disappeared by 1937” equals 1 for firms in the 1928 Moody’s Industrials manual that over the subsequent 10-year period were dropped from coverage for one of the following reasons: going bankrupt, liquidated, reorganized, foreclosed, dissolved, sold at foreclosure, no public interest, or due to Moody’s inability to find information on that firm. The

indicator variable “Acquired by 1937” equals 1 for firms in the 1928 Moody’s Industrials manual that over the subsequent 10-year period were dropped from coverage because they were acquired or merged with another firm. Cases in which the firm is the target of an acquisition vastly outnumber cases in which the firm merges with another firm: out of 326 firms that exit due to M&A activity 17.8% of firms are merged into another firm and 82.2% are acquired.

3 Other Cross-sectional Information

Office Location. We also obtain the data on the office location(s) of the firm, which always follows the information on the auditors and the annual meeting date for shareholders of the firm. Table 3 presents the office information that we parse out using natural language processing techniques, again for the first set of firms in the 1928 Industrials manual. We use this information to define state fixed effects (dummy variables equal to one for a given state if a firm has an office in that state; since a firm can have offices in several states, it can have several state dummies equal to one). We also use the state information to define firms as either rural (indicator variable “Rural” = 1) or urban (“Rural” = 0). The indicator variable “Rural” takes the value of one if the rural population in the state(s) in which the firm operates (defined using publicly available data from the 1930 U.S. Census) is in the top three quartiles of the distribution.

Industry Information. Pages xvii–xliv of the 1928 Moody’s Industrials manual contain details on “The Nation’s Basic Industries”. This section of the manual gives both tables with sales, production, wages, prices, as well as qualitative information on each of the industries. We augment this list of qualitative information for each industry with the information in pages xlv–lv, which includes an alphabetical index of “The principal commodities, industries, articles, etc, carried in this volume.”

The following list gives the 25 different industries we consider, together with the strings that we associate with each of the industries.

1. Steel and Iron: steel, iron, rolled, forge, slab, billet, tonnage.
2. Coal: coal, anthrac, bitumi, coke
3. Textile, Silk and Wool: textile, shirt, apparel, cloth, cotton, silk, wool, fall river, woolen, knit, yarn, cloth, worsted, towels, hosiery, fabric, laundr, wear, underwear, corset
4. Motor: motor, automo, airplane, aircraft, truck, road, tire.
5. Rubber: rubber, tires, tire fabric, belting.
6. Petroleum: petroleum, benzol, gasoline, crude, refin, oil, gas, tar, pipe.
7. Copper: copper, metal.
8. Equipment: equipment, car, bolts, freight, locomotive, railroad, valve, stove, passenger, foundry, machine, typewri, refrig, boiler, tubes, turbin, heater.
9. Sugar: sugar confect sweet.
10. Tobacco: tobacco, cigar, leaf, snuff, chew.

11. Packing: packing, cattle, hog, meat, sheep, animal, pork, beef, slaught, canned.
12. Shoe and leather: shoe, leather.
13. Retail trading: retail, store, grocer, music, piano, organ, grocery, candy, drug, mail.order, cigar.store, dry good, l.ght, neon, lamp.
14. Fertilizer: fertilizer, farm, crop, potash, phosph, nitrat, ammoni, sulphat, sulphur,
15. Shipping: ship, dredg, yards, dock, marine, ocean, idle tonnage, freight, charter, liner, boat, sea, steam, wharf.
16. Building: building, hardware, construct, lock, cement, lumber, asphalt, built, roof, asbesto, portland cem, glass, brick, plumb, realty, tile, tiling, paint, furnit.
17. Paper: paper, fibre, newsprint, print, pulp, wood, book, board, wrapping, bag, tissue, felt, timber, publish, press.
18. Food: food, grain, juice, molas, salt, soda, fruit, ice, butter, spice, soup, cream, milk, dairy, dairi, chocolat, coffee, cocoa, water, rice, bake, bakin, butcher, bottl, cereal, flour, beer, agricul, alcoho, beverag, biscuit, brew, wine, ale.
19. Manufacturing: manufact, mfg.
20. Entertainment: theat, fil, hotel, radio.
21. Mining: mine, mines, minin., gold, silver, zinc, bronze, lead, tin, nickel.
22. Electrical/Chemical: wire, cable, brass, power, electric, chemical, enginee, furnace.
23. Mills: mill, milling.
24. Storage: warehouse, storage.
25. Miscelanea: pharma, magnet, batteries, battery, signal.

We use regexes to decide whether a firm is in a given industry, checking the list of words for each industry against the whole entry for a given firm in the manual. We use the whole corpus of text we assign to a given company when defining industries. We note that in the above list the expressions between commas should be read as a regex (i.e., `l.ght` refers to strings that start with the letter “l,” followed by any other symbol, and then the string “ght”).

We use firm industry information to define industry fixed effects in the following way: we count the total number of words associated with an industry B appearing in the text for a given firm A. To define industry dummies, we set an indicator variable for an industry B of a given firm A equal to 1 if the count of words associated with the industry B in firm’s A text comprises at least 25% of the total industry words we identify in A’s text. Thus, similar to state fixed effects, a firm might have several industry dummies equal to one.

We validate our industry classification in the following way. We estimate the variation that our industry fixed effects explain in a corporate finance variable that is known to have large cross-industry differences – firm financial leverage. In particular, we estimate R^2 in an OLS regression where we explain firm leverage with our industry fixed effects. We find that our industry fixed

effects explain 8.3% of variation in firm leverage. These regressions are presented in Appendix Table 1. We then repeat this exercise with the COMPUSTAT/CRSP data. In particular, we use three cross-sections (to match the cross-sectional nature of our data) in 1980, 1990, and 2000. Using CRSP industry codes (which, unlike COMPUSTAT codes, are dynamic through time), we assign firms to Fama-French 30 industries, which are the closest in count to our 25 industry groups. We exclude financial firms and utilities, since these are not included in the industrial manuals and hence are not in our sample. This step leaves us with 28 Fama-French industries. We find that CRSP-derived industry fixed effects explain 4.5%, 5.4%, and 14.6% of variation in leverage for the 1980, 1990 and 2000 cross-sections, respectively. Comparing the R^2 in our and the COMPUSTAT samples, our industry fixed effects appear to explain a similar amount of variation in leverage to standard industry measures used in modern samples.

Table 1: OCR sample output from the 1928 Moody's Industrial Manual

The table reports the raw OCR output from ABBYY for two pages (from the top, cut for space purposes) from the 1928 Moody's Industrial Manual. See Figures 1 and 2 for the original image files.

OCR output for page 1 of the 1928 Moody's Industrial Manual

First Section
INDUSTRIAL COMPANIES
Including security ratings where complete facts and figures are available
ACME STEEL COMPANY
History Organized in 1880 and incorporated April, 1884, in Illinois, as Acme Flexible Clasp Co.; in 1899 consolidated with Quincy Hardware Manufacturing Co. as Acme Steel Goods Co.; changed to present title in 1926. Manufactures hot rolled hoop steel, barrel hoops, bale ties, bucket hoops, metal box straps, corrugated fasteners and hot and cold rolled strip steel. Plants located in Chicago and Eiverdale, Illinois, have a capacity of 700 tons per day. Chicago plant covers 2½ acres with total floor space of about 5 acres. Eiverdale plant located on site of 135 acres. Branches, offices and warehouses in New York, San Francisco, Los Angeles, New Orleans, Atlanta, Seattle, Vancouver, Winnipeg, Montreal and Detroit.

Table A—Bond Records	Interest Payable	Maturity	Authorized	Outstanding	Five Year Average Income	Interest Required Per Annum	Times Interest Earned	Security	Salability	Rating
1. Acme Steel Goods Co. 1st 6s.	M&S	Mr. 1943	\$3,500,000	\$1,381,000	\$1,424,359	\$82,800	17.2	High	Fair	A

1. Acme Steel Goods Co. first sinking fund gold 6s, series A:

Authorized—\$3,500,000; outstanding, \$1,381,000; retired to Dec. 31, 1927, \$119,000.

Dated—March 1, 1923; due March 1, 1943.

Interest Paid—M&S 1, at Trustee's office.

Trustee—Harris Trust & Savings Bank, Chicago.

Denomination—Coupon, \$500 and \$1,000; interchangeable; registerable as to principal.

Callable—At any time on 60 days' notice at 103 prior to March 1, 1933; at 102 prior to Mar. 1, 1938; at 101 until Sept. 1, 1942; thereafter at par. Bonds may also be purchased or called for the sinking fund (which see).

Sinking Fund—Semi-annually beginning Jan. 1, 1924, sufficient to retire 68% of the issue by maturity by purchase at not exceeding redemption price or if not so obtainable by call at that price. During the years 1928 to 1932 inclusive sinking fund payments shall amount to 3% of the total bonds of this issue; 1933 to 1937 4% annually; 1938 to 1942 incl., 5% annually.

Security—First mortgage on all fixed assets of the company now owned or hereafter acquired. Indenture provides that no cash dividends shall be paid on common except out of earnings, subsequent to January 1, 1923, and in no event when such action will reduce current assets below twice current liabilities, and that no additions to fixed assets shall be made which will reduce current assets below two and one-half times current liabilities.

Additional Bonds—May be issued for 60% of cost or value of additional property and permanent improvements provided net earnings for two years preceding date of proposed issue average at least three times total annual interest charges on all bonds outstanding and to be issued.

Tax Provisions—Company pays normal income tax up to 2%.

Offered—(\$1,500,000) at 99 in March, 1923, by Marshall Field, Gore, Ward & Co., New York.

Interest paid M&S 1 at Bank of Italy National Trust & Savings Association, San Francisco, Trustee. Coupon, \$500 and \$1,000. Callable on any interest date on 30 days' notice at 105 to Mar. 1, 1928 incl., and at ½% less each year or part thereof thereafter. Convertible into capital stock at any time prior to maturity, or if redeemed before maturity prior to ten days before the redemption date on basis of par for debentures and \$50 per share for capital stock, accrued interest on debentures to conversion date to be paid in cash. Sinking fund payable annually and cumulative beginning Mar. 1, 1929 of \$35,000. In event debentures are called for redemption and shall, subsequent to such call and prior to ten days before the redemption, be converted into capital stock, sinking fund shall be credited to that extent. Bonds at par may be tendered in lieu of cash.

A direct obligation of the company but not secured by mortgage. Company agrees that it will not mortgage any of its properties, nor create any other indebtedness except (a) purchase money obligations for property other than merchandise, including renewals and substitutions thereof, (b) indebtedness incurred in the usual course of business of no longer than six months' maturity and (c) additional authorized debentures. Additional debentures up to \$1,300,000 may be issued in one or more series provided net earnings for twelve months next preceding have been at least twice interest charges on debentures outstanding and to be issued, and further shall be issued only to reimburse company for not exceeding 50% of cost of capital improvements made since issuance of last debentures and shall be issued only when aggregate debentures outstanding and to be issued, shall not exceed 50% of net worth of company, including proceeds from such issue of debenture bonds and excluding bonded indebtedness. Issued for additions to plant, for expansion and for other corporate purposes. California not exceeding 5 mills taxes refunded. Company pays normal income tax up to 2%.

Offered (\$700,000) at par in Apr., 1927 by Blyth, Witter & Co., and Mitchum, Tully & Co., San Francisco.

CAPITAL STOCK: 1. Mutual Stores, Inc. stock: Authorized, 150,000 shares; outstanding, 110,000 shares; reserved for conversion, 40,000 shares; no par.

MYERS (F. E.) & BRO. CO.: Incorporated under Ohio laws in 1927 to succeed company of same name incorporated in 1920. Business established in 1878. Manufactures pumps of various types and sizes, water systems for domestic and industrial use, automobile washers, spraying units, hay tools, door hangers, etc.

MANAGEMENT: OFFICERS: P. A. Myers, Pres.; J. C. Myers, G. C. Myers, A. N. Myers, G. D. Myers, Vice-Pres.; F. B. Kellogg, Sec. and Treas., Ashland, O. DIRECTORS: P. A. Myers, J. C. Myers, G. C. Figure 3: Image of page from the 1938 Moody's Industrial Manual with the list of firms dropped from coverage over 1928-1937.

Table 4: Industry Classification Validation

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The dependent variable is firm financial leverage (debt scaled by assets). All variables are measured as of 1928. Firm age is measured as 1928 minus the year of establishment. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

for

“Friends during Hard Times: Evidence from the Great Depression”

In this Appendix, we report the results of additional tests to support the analysis in the main text. First, we provide additional robustness analysis of our main result that director network connections predict a significant reduction in the probability that a firm fails during the Great Depression. Next, we present additional analysis to support the instrumental variables approach that we discuss in Section 3.3 of the main text. Then, we provide more details on a number of tests that we briefly describe in the main text, including our analysis of the potential banker-director and equity infusion mechanisms from Section 4.

1. Baseline Analysis: Additional Robustness Checks

In this Section, we expand upon the robustness checks of our baseline tests that we briefly described at the end of Section 3.1 of the main text.

1.1. Cox Proportional Hazard Model

First, we re-estimate our baseline regressions within a Cox Proportional Hazard Model. This approach allows us to account for differences in the timing of failure across firms over the 1929 to 1937 window. In our dataset, the distribution of firm failures over time mirrors changes in macroeconomic conditions during the Depression period. We observe an increasing failure rate in 1929 reaching a local peak in 1930. We observe another peak in 1934, but then failure rates decline as the economy improved during the 1935-1936 period. Failures begin to increase again in 1937, corresponding with the onset of another recession period. We replicate each regression

specification from Table 3 of the main text, with no changes to the set of included independent variables. Because our independent variables do not vary with time, our estimates can be interpreted as shifting the baseline hazard function for failure up or down. We report coefficient estimates as odds ratios. Thus, factors that improve survival probabilities have coefficient estimates less than 1. We report the results in Online Appendix Table 1. The results mirror the results from the OLS specifications in Table 3 of the main text. For example, the estimates in Columns 2 and 5 imply that firms with more connections than the median firm have survival rates that are 18% to 19% higher than other firms, effects very similar in magnitude to what we observe in the OLS specifications.

1.2. Control for Firm Performance

Next, we tabulate the results of reestimating our baseline specification (Equation (1) in the main text) including 1928 net income scaled by assets as an additional control variable. Our main specification uses differential responses to a major unanticipated financial shock among connected and unconnected firms to identify the effect of connections on firm survival. Though this strategy directly addresses reverse causality concerns that would plague a simple regression of survival on network ties, it does not solve all potential endogeneity concerns. The biggest threat to identification is that connections correlate with an omitted variable that itself predicts more resilience to the financial shock. An obvious way to address the concern that connected firms could simply be better than unconnected firms is to control for ex ante profitability. We do not do so in our main regressions because we only observe usable income statement information for roughly 70% of our sample firms. However, as a robustness check, we include the ratio of net income to assets to control for ex ante differences in firm quality. While this ratio is not an ideal measure of return on assets (net income is net of interest payments to creditors), we also control directly for

leverage, which should mitigate the concern. We do not use sales as the numerator because sales information is even less reliably reported in the 1928 Manual. We tabulate the results in Online Appendix Table 2. Despite the noise in the measure, we find that ex ante net income is a strong negative predictor of failure during the Depression. The coefficient estimate on the control is statistically significant at the 1% level in all specifications. Economically, a one standard deviation increase in scaled net income is associated with a 5.8 percentage point decline in the likelihood of firm failure (or a nearly 40% reduction in the likelihood of failure from the baseline rate). These estimates validate the quality of the control, despite the measurement challenges outlined in the text. Yet, including the control does not have a major effect on our estimates of the effect of director network connections on firm survival. The point estimates are generally slightly larger in magnitude (and statistical significance) than those we report in Table 3 of the main text. An exception is the estimated effect of director connections that fall in the top quartile of the distribution. After we control for ex ante performance, we estimate an effect of top-quartile connections that is roughly double the magnitude of the estimate in Table 3 and statistically significant at the 5% level. This difference in estimates is consistent with the discussion in the text that firms in the top quartile of the connections distribution appear to be disproportionately firms whose characteristics predict low failure rates (large, public, cash-rich and, here, profitable).

1.3. Control for Firm Age

Though our control for ex ante performance addresses the possibility of an omitted factor that correlates with network connections and predicts generally better performance, it is still possible that an omitted factor that correlates with connections, but only matters for performance precisely during bad economic times could threaten the causal interpretation of our estimates. One possible confounding factor is firm age. Older firms could be more likely to employ connected

directors and also more likely to have the resources to weather a major financial shock, even if they perform similarly to other firms in normal markets. For example, they could have longer relationships with lending banks or other outside investors that make them less prone to face financing constraints during a crisis. To address this concern, we supplement the regressions in Table 3 with a control for the natural logarithm of firm age.¹ We find some evidence that older firms are indeed more likely to survive (the coefficient estimate on age is negative and marginally significant in the specifications that include industry and state fixed effects, but not significant when these fixed effects are not included). However, our estimate of the network effect is virtually unchanged. We present the results in Online Appendix Table 3. We also test the robustness of our result to a less parametric age control, including indicator variables for twenty bins of the firm age distribution, with similar results. Overall, the economic factors captured by firm age do not seem to explain the link between director connections and firm survival.

1.4. Control for Director Expertise

Another possibility that is not directly addressed by our baseline controls or, potentially, the control for ex ante firm performance is that directors on boards with more connections also have other specific skills that matter precisely for navigating the firm through a crisis. For example, director financial expertise could be irrelevant to firm performance in normal times, but help the firm to access scarce finance precisely during a major negative financial shock. Though we do not observe background information on directors in the Moody's manual, we use the information on positions that directors hold in other Moody's firms to construct proxies for director skills. Specifically, we construct firm-level controls for the percentage of directors who (1) serve as

¹ We do not include firm age in our base set of controls again because missing data results in additional sample attrition with no material changes to the estimates of interest.

executives in other firms or (2) serve as financial executives in other firms (i.e., Treasurer).² Since both proxies require a director to hold positions in other firms, they are by construction positively correlated with our measure of network connections. Nevertheless, neither of them have significant explanatory power for firm survival. Moreover, the effect of network connections on survival is similar if we include either proxy as an additional control in Equation (1). We present the results in Online Appendix Table 4. Though there could of course be other specific director skills that matter for survival and for which we do not directly control, it is easiest to generate concerns about financial skills given the totality of our results. Thus the fact that we find virtually no effect on our key estimates from including controls for such skills also mitigates the more general concern.

1.5. Controls for Other Local Factors that Influence Firm Survival

Though we include state fixed effects in our Table 3 specifications, it is possible that features of the economy or financial environment that vary within states could correlate with the network connections that firms form and their likelihood of surviving through a major financial crisis. One such factor is the policy response of the government within the years over which we measure firm survival. We investigate the role of the Reconstruction Finance Corporation (RFC), a government agency that was established in 1932 to provide financial assistance to financial intermediaries and businesses, among other objectives. We control for within-state variation in the intensity of aid dispensed to firms using county-by-county data on RFC spending between 1933 and 1937 compiled by Fishback, Kantor, and Wallis (2003). We report the results in Online Appendix Table 5. In Column 1, we include the natural logarithm of county RFC spending as an additional control in the specification from Column 5 of Table 3 in the main text. In Column 2, we

² Treasurer appears to be the 1920s analog of the modern Chief Financial Officer.

include an indicator for counties in which RFC spending is above the sample median so that we define the extra control in a way that is parallel to the definition of our connections measure. We do not observe a significant effect of RFC spending on firm survival probability in either specification. However, the estimates of the RFC effect should be treated with caution because it is likely that spending negatively correlates with economic health of the county. More importantly, including these controls has virtually no effect on the magnitude or significance of the effect of network ties (despite the loss of some observations due to a lack of a county-level match). We also find no evidence that network connections have a differential effect in counties with more or less RFC funding.

Another factor that could correlate with both network links and firm failure rates during the crisis is local agglomeration economies. Instead of attempting to measure these effects directly, we partial them out by including major city fixed effects in our baseline regression specification (Column 5 of Table 3). Agglomeration economies are likely to be the largest in the major business centers of the era. Thus, we include fixed effects for 15 cities that had local stock markets in 1928: New York, Chicago, Boston, Philadelphia, Baltimore, Cincinnati, Detroit, Cleveland, Hartford, Honolulu, Los Angeles, Louisville, Pittsburgh, San Francisco, and St. Louis. Roughly 52% of the firms in our sample have an office in at least one of these cities. By including a dummy variable for each city, we correct for city-specific differences in the prevalence of network connections and the firm failure rate during the crisis. We report the results in Column 3 of Online Appendix Table 5. Again, the added controls have virtually no effect on the estimated effect of network connections on firm survival, suggesting that network connections matter independently from city-level agglomeration economies. In unreported estimations, we also test for interactions between the two factors, but do not find any evidence of significant effects.

2. Instrumental Variable Analysis

Our IV strategy relies on exploiting differences in the local demand for directors' services across states (and industries). We begin by providing evidence to support this assumption; that is, we measure the segmentation of director markets within our 1928 sample. In Online Appendix Figure 1, we present a visual representation of the geographic distribution of the network. Each vertex represents an industrial firm from the 1928 manual. We use colors to distinguish firms that are located in different Census divisions.³ In our data, the divisions with the most sample firms (in descending order) are the Middle Atlantic (which includes New York and is indicated in purple), East North Central (which includes Chicago and is indicated in green), New England (which includes Boston and is indicated in pink), and the Pacific (which includes California and is indicated in yellow). From the picture, it is evident that there is geographic clustering of firms within the network. Firms in the Pacific cluster in the upper right, while firms in New England cluster in the upper left. Firms in East North Central cluster towards the bottom of the graph and, intuitively, firms in the Middle Atlantic cluster near the center. Moreover, we observe several small, disconnected networks around the perimeter of the main network and we omit roughly a quarter of the firms from the diagram because they do not have any network connections.⁴ Thus, in addition to clear variation in degree centrality across firms, there appears to be substantial network segmentation that we can use as a source of identification.

Our identification relies on differences across industries within a state in average board sizes (or, alternatively, differences across states within an industry). It is tempting to conjecture

³ The nine Census divisions are Pacific, Mountain, West North Central, East North Central, New England, Middle Atlantic, South Atlantic, East South Central, and West South Central. See https://www2.census.gov/geo/pdfs/maps-data/maps/reference/us_regdiv.pdf for the detailed mapping of states to divisions.

⁴ These features are not as prominent in more recent data. See, e.g., Fracassi (2017) for an analogous diagram of the 2005 network of firms. Some of the difference could reflect geographic clustering due to higher travel costs. Some of it could also reflect our inclusion of private firms.

that our instrument – which exploits differences in average board sizes across industries within a state (or across states within an industry) – is just a proxy for whether a state is urban or rural, or alternatively for the overall market activity in the state. This type of intuition is incorrect. For example, consider the distinction between urban and rural areas. Geographic segmentation of markets only predicts that there are constraints on the ability of directors to serve at multiple firms across large distances. However, a firm in an urban environment could still face constraints on the availability of local experts if there are few other local firms in the industry or if local firms in the industry happen to have small boards. For example, a cotton mill in New York could operate in a *Low* industry, while a cotton mill in Georgia does not. Conversely a bank in Georgia might be in a *Low* industry, while a bank in New York is not. We observe variation in *Low* both across industries within a state and across states within an industry.

To demonstrate the nature of the variation we exploit more directly, we construct a heat map of the fraction of industries in each state in which *Low* takes the value 1. We present the map in Online Appendix Figure 2. Confirming the above discussion, there is a wide distribution of *Low* industries geographically. Most states have at least one *Low* industry. Some urban states with many industries also have relatively large numbers of *Low* industries (e.g., New York), while some rural states with few industries have relatively small numbers of *Low* industries (e.g., Kansas).⁵ On the other hand, some urban states have relatively few *Low* industries (e.g., Maryland) while some rural states have relative many (e.g., Colorado). Overall, the map demonstrates that there is no obvious regional pattern that could explain the variation captured by *Low* and undermine the exclusion restriction necessary to interpret the results causally.

⁵ We define “urban” and “rural” states using data from the 1930 U.S. Census. See the discussion in Section 4 and footnote 20 for a list of urban states.

As we noted in the main text, the relative magnitude of our IV estimates compared to the OLS estimates of the network effect could raise concerns about the validity of the instrument. There, we discuss why endogeneity could obscure the relation between network ties and firm failure in OLS specifications. Moreover, we note the large heterogeneity in the effect of networks that we observe in our sample so that a local average treatment effect that exceeds the population effect is not altogether surprising. However, another possibility is that the inflation in our estimates is a symptom of a weak instrument, despite the sizable first stage explanatory power. Here it is noteworthy that the instrument does not produce estimates that are economically or statistically significant if we consider the probability of being acquired as the dependent variable rather than the indicator for firm failure (See also footnote 18 of the main text).

To explore these possibilities further, we experiment with a more flexible specification of the instrument. Instead of partitioning the sample into thirds using the fraction of the local director pool that works at within-industry firms, we partition the sample into sixths and define indicator variables for each partition. We then re-estimate the IV specification from Columns 4 and 5 of Table 5 using subsets of the indicator variables as instruments in place of *Low*. Specifically, we first include only the indicator for the bottom sextile, then progressively add the indicators for additional sextiles, in order, until we include indicators for all but the top sextile as instruments. When we include indicators for the bottom two sextiles, we find essentially the same result we report in Table 5 (unsurprisingly). As we continue to add additional instruments, the F statistic for the joint significance of the instruments declines. When we saturate the model with indicators for the bottom five sextiles, all five instruments are individually significant at the 5% level (the bottom two, which correspond to *Low*, each at the 1% level). However, the F statistic drops to 5.82. Thus, we have greater concern about weak instruments. Nevertheless, the second stage coefficient

estimate on the indicator for high network connections declines in magnitude to -0.296 (p -value = 0.08). This analysis is consistent with the interpretation of the IV estimates in Table 5 as a local average treatment effect on a portion of the sample in which the effect of network connections on failure is larger. Using additional variation in network connections that is predicted by a less extreme part of the distribution of local market depth results in an estimated effect that is smaller in magnitude, despite producing a weaker set of instruments. Nevertheless, the size of the differences in estimates relative to our baseline OLS specifications suggests caution and the validity of the IV estimates ultimately rests on the validity of the exclusion criterion.

3. Additional Evidence on Economic Mechanisms

In Section 4 of the main text, we present additional tests to shed light on the economic channel(s) through which network connections facilitate firm survival during the Depression. In Section 4.3, we discuss our approach to test whether network connections particularly matter among financially constrained firms because connected directors are actually banker directors (or correlate with the presence of such directors). In particular, we recompute network connections restricting attention only to directors who also serve as executives of industrial firms. And, we drop firms from the sample that had outstanding bank debt or mortgages in 1928. In Online Appendix Table 6, we present the estimates of the cross-sectional specifications from Table 6 of the main text after imposing both of these restrictions on the data. In all cases, the estimates of the effect of network connections are very similar to those we report for the corresponding specifications in Table 6.

In Section 4, we also discuss direct equity infusions via acquisition as a potential channel through which network connections could facilitate the flow of financing to constrained firms. We show in Table 13 that network connections are indeed associated with a higher likelihood of being

an acquisition target during the Depression years. We also discuss additional analysis in which we replicate the cross-sectional analysis from Table 6 in the context of acquisitions. Specifically, we test whether this acquisition effect is also more pronounced among small, private, rural, and/or cash poor firms (like the effect of networks on firm survival). We present the results of this analysis in Online Appendix Table 7. We do not find any evidence of cross-sectional differences except when we compare private to public firms. We do observe that private firms in which directors have more connections than in the median firm have a significantly higher probability of being acquired. Interestingly, we also do not observe that any of the proxies (with the exception of firm size in one specification) have significant level effects on the probability of being acquired. So, perhaps puzzlingly, firms most likely to be financially constrained are not more likely to be acquired than peers nor do connections facilitate such firms' participation in the market for corporate control.

Online Appendix Figure 1. The figure presents a graphical representation of the network of directors and executives in the sample of industrial companies from the 1928 Moody's Industrials manual. Subsidiaries and foreign companies are excluded from the network. The diagram does not include 746 firms that do not have any connections to other firms, though they are included in the analysis. The representation is an energy diagram created using the 2D Fruchterman-Reingold algorithm. Colors indicate the Census division in which the firm is located. For firms with multiple offices, we classify the firm in the region in which it has the most offices. Colors map to regions as follows: Pacific - Yellow, Mountain - Lime Green, West North Central - Blue, East North Central - Forest Green, New England - Pink, Middle Atlantic - Purple, South Atlantic - Red, East South Central - Orange, West South Central - Brown.

Online Appendix Figure 2. The figure reports the percentage of industries operating in each state for which the instrument Low is equal to one. Low is an indicator variable equal to one if the number of directors in a firm's industry-state pair as a fraction of the number of directors in the state is less than the sample 33rd percentile. Darker shades indicate a higher fraction of Low industries in the state.

Network Connections and Firm Failure: Cox Proportional Hazard Model

Coefficient estimates are from Cox Proportional Hazard Model regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. Coefficient estimates are presented as odds ratios. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm does not survive to 1937. Total Connections is the sum of connections to other firms in the sample via shared directors or managers. Total Connections > Median is an indicator variable equal to one for firms that have a value of Total Connections greater than the sample median. Total Connections Quartile 2 (3/4) is an indicator variable equal to one for firms that have a value of Total Connections in the sample 2nd (3rd/4th) quartile. Private is an indicator variable equal to one for firms without publicly traded equity. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.

Network Connections and Firm Failure by Firm Characteristics: Only Executives and No Bank Loans or Mortgages

Coefficient estimates are from ordinary least squares regressions on the sample of firms from the 1928 Moody's Industrials manual, excluding foreign firms and subsidiaries. The sample also excludes all firms with outstanding bank loans or mortgages in 1928. The dependent variable is Disappeared by 1937, an indicator variable that takes the value one if the firm no longer exists in 1937. Total Executive Connections > Median is an indicator variable equal to one for firms that have a value of Total Executive Connections greater than the sample median, where Total Executive Connections is the sum of connections to other firms in the sample via shared directors or managers. To form a connection a director must appear in a management position in a firm in the 1928 Moody's Industrials manual; shared directors who do not hold a managerial position in an industrial company do not count as connections. Private is an indicator variable equal to one for firms without publicly traded equity. Rural is an indicator variable equal to one for firms that have offices only in counties in which the rural population in 1930 is greater than 60%. Low Cash (Small Firm) is an indicator variable equal to one for firms that have Cash/Assets (Total Assets) less than the sample median. Total Assets, Debt/Assets, and Cash/Assets are winsorized at the 1% level. Standard errors that are robust to heteroskedasticity are reported in parentheses. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively.
